Synchrotron radiation is the continuous electromagnetic radiation produced by a highly relativistic plasma in a magnetic field. It can cover a very broad range of wavelengths, from gamma rays to radio wavelengths. In a magnetized ► [plasma](#), an electron gyrates around the direction of the magnetic field because of the Lorentz force and thus radiates as does any accelerated charge. When electrons reach highly relativistic speeds, the emission comes from a narrow beam in the direction of motion, so that the observer sees extremely narrow pulses whose resulting spectrum is a continuum spread over a very broad range of frequencies. The slope of the spectrum is characteristic of the electrons' energy distribution. Synchrotron emission is seen in extreme energy environments such as the accretion disks around ► [black holes](#), ► [neutron stars](#), and some ultra-massive black holes at the centers of galaxies. This type of radiation is called *nonthermal*, as opposed to *thermal* radiation such as ► [blackbody](#) or free-free emission.

Syngenicity

Nicola McLoughlin

Department for Geology, Rhodes University,
Makhanda (Grahamstown), South Africa

Keywords

Antiquity · Biosignatures

Definition

Syngenicity means a feature that may be textural, chemical, mineral, or biological and that formed at the same time as the encapsulating material. In other words, a primary component that is preserved contemporaneously with the deposition of the host-sedimentary rock, or crystallization of the host igneous melt, or precipitation of the encapsulating mineral or ice phase(s). The demonstration of syngenicity is equivalent to the demonstration of antiquity, and this is essential to establish the history of life in our universe.

History

In economic geology, the term syngenetic has traditionally been used to refer to ore deposits formed at the same time as the enclosing rock as opposed to epigenetic that describes mineral deposits formed later. Here, a definition is provided that is more generally applicable to the investigation of astrobiological materials including not just terrestrial rocks and minerals but also meteorites, interplanetary dust, and ice particles.

Overview

A syngenetic textural, chemical, mineralogical, and/or biological component is formed at the same time as the host material. Syngenetic components of low-temperature deposits are those that were stable at the ambient pressure, temperature, redox, and salinity conditions prevailing at or near

the planetary surface at the time of formation. In the case of high-temperature volcanic rocks and precipitates, syngenetic components formed in equilibrium with the solidifying magma or fluid, for example, primary melt or fluid inclusions, and mineral phases. Syngenicity concerns the source of a component in time. This differs from ► [endogenicity](#) that concerns the source of a component with regard to space. Components that are syngenetic are nearly always also endogenetic, that is, derived from within the system. There are a few exceptions, however, for example, windblown ash particles preserved in ice cores, or pollen grains entombed within desert varnish crusts.

The demonstration of syngenicity is equivalent to the demonstration of antiquity, and this is especially important to establish the history of life on planetary bodies (e.g., Wacey 2009). Syngenetic components are found within early phases in the host material and do not occur in late-stage alteration products or crosscutting veins, and this can be tested by microscopic examination of thin section. Thus, for example, microbial remains found in superficial cracks, late-stage veins, or metastable minerals are unlikely to be syngenetic and rather, more likely, to be derived from subrecent organisms (e.g., Westall and Folk 2003). Syngenetic components should also have experienced the same degree of deformation and alteration as the host rock. Thus, for example, spherical structures should be flattened parallel to the regional deformation fabrics if these exist (e.g., Appel et al. 2003). Moreover, the distribution and abundance of syngenetic components in a system should reflect primary environmental gradients such as light levels or redox gradients. This can be investigated by meter- to micron-scale mapping to establish if there is a correlation between primary depositional or magmatic variables and the distribution of the candidate biosignatures. Sometimes it is possible to measure an absolute radiometric age for the feature of interest (e.g., Grosch and McLoughlin 2014) who used U-Pb dating to establish the age of microtextures comprising the mineral titanite CaTiSiO_4 , or more commonly the phase of interest can be relatively dated to mineral cements or veins of known age and placed within the chronology of processes that have affected the whole system.

Definition

Synthetic tissues are relatively simple materials that carry out one or more of the functions of natural tissues. Synthetic tissues could provide a medical or surgical lifeline during space travel or on a distant colony. Functional synthetic tissues

might also provide clues about the origins of multicellular life. Hybrid tissues formed between synthetic tissues and natural or edited living cells will create materials with higher functions or form the basis of personalized implants. The manufacture of such materials for use on Earth might be improved in microgravity.

Overview

Synthetic Tissues

While a significant body of work now describes synthetic cells, relatively little work has been done on synthetic tissues. By “tissue,” we mean a multi-compartment system in which the compartments can communicate with each other and with the external environment, thus constituting a material with emergent properties, the sum being greater than the parts. We have devised a simple approach to such systems in which networks of 3D-printed picoliter droplets are formed in oil (Villar et al. 2013). The droplets are separated from one other by single lipid bilayers, which provide interfaces through which the compartments can communicate assisted by membrane proteins (Bayley et al. 2019). While other approaches are possible, our system illustrates the requirements and qualities of synthetic tissues.

Synthetic tissues are required to carry out one or more of the functions of natural tissues. 3D-printed droplet networks have been produced that can transmit electrical signals and change shape, thereby mimicking nerves and muscles (Villar et al. 2013). Recent work has shown that such structures can receive and process external signals, presaging the genesis of sophisticated functionality (Booth et al. 2016; Downs et al. 2020). Droplet networks can be transferred from oil into a purely aqueous environment by a variety of means (Alcinesio et al. 2021), allowing applications in biology and medicine.

Printed Cells

The construction of tissues by the 3D printing of living cells has been investigated for at least 20 years (Murphy and Atala 2014; Heinrich et al. 2019; Zhang et al. 2021). Most work has

been done with printers in which a “bioink” is extruded like toothpaste from a tube. We are using a droplet-printing approach similar to that used for synthetic tissues (Graham et al. 2017; Zhou et al. 2020). While the process is slow, and improvements in this regard are forthcoming, it has the ability to perform high-resolution patterning, and it is compatible with the construction of soft tissues, such as that of the brain. Further, cells can be printed at high density and with high viability in naturally derived extracellular matrix, and after printing they remain able to divide, differentiate, and migrate (Zhou et al. 2020). The approach is amenable to a wide variety of cells and, given advances in stem cell technology and genome editing, we find ourselves at an especially exciting juncture for 3D tissue fabrication.

Hybrid Tissues

The formation of hybrids between synthetic tissues and natural or edited living cells and tissues has the potential to create materials with higher functions or that form the basis of personalized implants. Communication between the components of the hybrid tissues might be direct: for example, through proteins that resemble gap junctions (Mantri et al. 2013), or between compartments and cells that are not in contact through a paracrine system. The structures and functional properties of such materials are limited only by imagination.

The Origins of Multicellular Life

The origins of life are a primary concern of astrobiology. Despite the considerable experimental work on synthetic cells, “protocells” in the origins field, there has been little effort on the discovery of the origins of multicellular organisms. Many researchers consider that “prototissues” would have been generated by the aggregation of protocells. Nonetheless, the formation of droplet networks in oil should be considered as a precursor of multicellular organisms, especially since the oil can be readily removed to yield multi-compartment structures in an aqueous environment (Deng et al. 2016; Alcinesio et al. 2021). Cooperative functions may have emerged in these structures in which the compartments are

separated by individual lipid bilayers, before double-bilayer compartmentalization appeared, further down the evolutionary pathway.

Manufacture in Microgravity

The manufacture of synthetic tissues, printed cells, and hybrid tissues might be improved in microgravity. Indeed, there is a long list of companies engaged in the manufacture of a variety of materials in space, supporting this conviction [www.factoriesinspace.com/manufacturing-companies]. For example, soft tissues generated by printing cells might be stabilized in a microgravity environment until the extracellular matrix enveloping the cells has gelled (Zhou et al. 2020), strengthening the materials sufficiently for return to earth. The production of larger structures might be less problematic, because of the decreased tendency to deform under microgravity. Improvements in the precision of 3D printing of synthetic tissues are also required (Alcinesio et al. 2020), which might also be aided by microgravity.

Materials for use in space or extraterrestrial colonies that might be produced by synthetic tissues or printed cells include fuels, gases, biopolymers, and pharmaceuticals (Menezes et al. 2015). The production of food in space, including meat from cultured cells [e.g., www.meatable.com], is also an attractive proposition that could exploit printing technologies.

Experimental Science in Microgravity

Printed cells might contribute to investigations of fundamental space biology. After printing, eukaryotic cells can divide, differentiate, and migrate (Zhou et al. 2020). Further, stem cells and genome-edited cells can be used to form 3D tissue constructs, which can be printed in natural or unnatural arrangements, suggesting a plethora of experiments that might be performed to test the effects of low gravity or radiation on developing and mature mammalian tissues. Printed tissues might also be used to test therapies that could be affected by the space environment, such as treatments for wound healing.

Recently, we examined “warfare” between strains of bacteria patterned by printing (Krishna Kumar et al. 2021). Similar approaches will allow

various aspects of the properties of microbiomes to be explored under microgravity and in extreme space environments. Indeed, the effects of the space environment on all manner of cells patterned in two- or three-dimensions could be examined.

Synthetic and Hybrid Tissues for Space Medicine

Synthetic tissues could provide a medical or surgical lifeline during space travel or on a distant colony. Modern medical treatments include cell-based therapies (e.g., immunotherapies) and tissue and organ transplantation, and all but the most mundane treatments will have to be manufactured on demand during space travel or in distant colonies (Snyder et al. 2019). Complex treatments will most likely be mediated by robotic telemedicine procedures. It will be necessary for spacecraft to carry a minimal “larder” of chemical and biological reagents that can in turn be used to service a full range of medical and surgical needs (Menenez et al. 2015). For example, hybrid tissues formed from synthetic tissues and natural or edited living cells might form the basis of personalized implants requiring the growth and differentiation of stem cells derived from the space travelers themselves. Small molecules required for such endeavors might be generated by programmable synthetic devices (Steiner et al. 2019) and growth factors, and other biologicals would be produced from cells (Menenez et al. 2015) including 3D cultures. Besides droplet printing, other approaches might be advanced or amalgamated for bringing cells together under microgravity, including versions of magnetic bioassembly (Parfenov et al. 2020) with improved resolution and patterning capacity.

Additional medical requisites that might be produced by printing and related technologies include tailored microbiomes as therapeutics and personalized microtumors for the evaluation of treatment regimens with available agents.

Constructive biology

Definition

Synthetic biology is a biological study, in scientific and engineering fields, depending on the construction of biological systems. A living organism is a system containing multilayers such as cells, biomacromolecules (proteins, RNAs, and DNAs), and monomers (amino acids and nucleotides). Because the numbers of combinations are huge, few combinations have been tried throughout the history of the Earth. Through realization of synthetic biological systems which represent what life could be, synthetic biology allows evaluation of models and hypotheses formulated from observations. Synthetic biology thus uses the complementary approach to the analytical approach which has been used in traditional biology.

Overview

Synthetic biology relies on accumulated biological information from comprehensive analyses such as genomics and on the development of technologies for the preparation of biomolecules. One example is the creation of a bacterial cell controlled by a genome derived from chemically synthesized DNA (Gibson et al. 2010). Although the genome sequence of this “artificial cell” is only slightly modified from the natural one, researchers can now obtain genome DNA with any sequence. In another field of artificial cell study, synthetic micro-containments consisting of lipid molecules encapsulate proteins and/or nucleic acids which confer a part of cellular function (Szostak et al. 2001; Chen et al. 2005; Sunami et al. 2010).

Due to the tremendously huge combination of bio-components, synthetic biology allows realization of biosystems with different properties from the one universally shared by the present life. Although natural ribozymes show a limited range of catalytic diversity, artificial evolution of RNA has uncovered a wide range of activity of aptamers or ribozymes (Ellington and Szostak 1990). Creations of genetic codes containing 21 amino acids (Wang et al. 2001; Kiga et al.

2002) or less than 20 amino acids (Amikura and Kiga 2013) assist the discussion for possible codes on exoplanets or evolution toward the universal genetic code. Such a huge combination, however, invokes two potential problems.

One problem is the rarity of combinations with a proper function. Not only the ratio of amino acids sequences with biological function to that without function, but the ratio of functional biosystems containing multiple macromolecules to nonfunctional biosystems is so small that realization of the functional ones requires evolution through a long time or a rational design process. Mathematical modeling for biological systems leads to fundamental understanding in systems biology and predicts behavior of a designed system in synthetic biology. Designed genetic circuits thus have given living cells programmed bistability (Gardner et al. 2000) or population control via cell-cell communication (Sekine et al. 2011). Through modeling in synthetic biology, furthermore, researchers can estimate the difficulty in construction of a designed system.

The other problem is that systems without correlation to the systems in exoplanet environments or in the past Earth can be created. Thus research on the environmental conditions of exoplanets or the past Earth is crucial for applications of synthetic biology to astrobiology, in order to provide appropriate constraints.

Overview

Historical

The knowledge of the age of the Earth and of the Solar System has always been a fundamental

question not only for scientists but also in most human cultures. The possibility of finding a solution to this question emerged in the beginning of the twentieth century with the discovery of radioactivity. The probability of transformation (the decay) of a radioactive nuclide (the parent) into a stable nuclide (the daughter) is constant, so that the ratio between a quantity of the parent and that of the daughter is only a function of time. Temperatures or pressures that are reached during geological or planetary processes (including formation processes) can alter this natural clock. Since all rocks contain traces of natural radioactive elements, the age of a rock can be obtained by measuring the present-day quantity of parent and daughter isotopes, provided daughter isotopes accumulated in mineralogical sites via the decay of their parent were never transported away.

Although in principle a simple task, the determination of the age of a rock relies on a precise measurement of the isotopic ratios of the element that contains the daughter nuclide. Since radioisotopes are present only in trace amounts in most natural samples, the routine determination of the age of a rock was not possible before the early 1960s. The age of the Earth cannot be measured directly because tectonics, erosion, and weathering have eliminated any primordial sample. The age of the Solar System, in contrast, was determined in 1956 by Claire Patterson as the uranium-lead age of chondrites (undifferentiated meteorites) and iron meteorites (Patterson 1956). It is remarkable that this age is still valid within its error bars (4.54 ± 0.07 Ga; $1 \text{ Ga} = 10^9$ years). What we know of the age of the Earth comes from extinct radioactivities: the age of the Earth cannot be different by more than a few Ma from the age of the other planetary objects of the Solar System, such as chondritic meteorites. The Apollo missions returned some samples from the lunar mantle which turned out to be hardly younger than the age of the Solar System, 4.43 Ga. It is therefore accepted that this age of 4.55 Ga characterizes the formation of the Solar System. The age of the Sun calculated from nuclear physics is compatible with this value but is known only to within ± 0.15 Ga. A consequence of all these observations is that the formation of the Solar System took

place within a time span of 0.1 Ga, i.e., faster than what can be defined by the analytical precision achievable 25 years ago.

The short duration of the formation of the planets prompted a massive technological effort in geochemical laboratories, beginning in the late 1980s. The motivation was to reach a precision on isotope ratios allowing us to distinguish events differing in time by a period of the order of 0.001 Ga but 4.5 Ga old! This is now achieved. New problems have nevertheless emerged simply because understanding the significance of an age measured with such a relative precision ($\pm 0.2\%$) is an unprecedented challenge in cosmochemistry.

Before addressing these problems, we review the analytical methods commonly used to date events that took place during the condensation of the first solids, their accretion to form small *planetoids* (sometimes referred to in the literature as planetary embryos or also as ► [planetesimals](#)), and the assembly of these small planetoids to form the present-day planets. Each of these stages has an age that can be deciphered in minerals.

The Concept of Radiometric Ages

The general law of radioactivity (see the detailed treatment of this problem by Albarède 2003) is written as $P = P_0 \exp(-\lambda t)$. P and P_0 are the number of parent atoms at time t and at time 0, respectively, and λ is the decay constant, which is equal to $\ln 2$ divided by the half-life $T_{1/2}$ (see ► [Decay Constant](#), ► [Half-Life](#)). In cosmochemistry, long-lived ($T_{1/2} > 200$ Ma) and short-lived ($T_{1/2} < 200$ Ma) radioactivities are distinguished because most radioactive isotopes formed with the solar nebula have now disappeared. Short-lived isotopes are therefore “extinct,” although minute amounts may be created by interaction of galactic cosmic rays with planetary atmospheres. The surviving long-lived nuclides may be used to obtain *absolute ages* – i.e., ages expressed relative to today – while short-lived systems are used to obtain *relative ages* between different objects. Because of their fast decay, the resolution in time offered by extinct radioactivities is usually much finer with short than with long-lived systems. In other words, the absolute ages of events dated by extinct isotopes are not known, but their

time difference is accurately known. ^{235}U has an intermediate status because its half-life of 704 Ma gives the ^{235}U - ^{207}Pb absolute ages a particularly high precision.

An absolute age is derived by combining the law of radioactivity and the rules of mass balance, and because thermal equilibration homogenizes isotopic abundances and not elemental concentrations, the chronometer is formulated in terms of isotope ratios (see Chronology) where the normalizing denominator isotope is stable: $P_0 - P = D - D_0$. D stands for daughter isotope – the stable element resulting from the decay of P . In this equality, the initial quantities P_0 and D_0 are unknown since we have only access to the present-day concentrations. Using the radioactive law defined above, we derive $D = D_0 + P \exp(\lambda t - 1)$. Taking the example of the long-lived radioactive nuclide ^{87}Rb , which decays to ^{87}Sr , we have, using ^{86}Sr to normalize the concentrations, the equation

$$(^{87}\text{Sr}/^{86}\text{Sr})_t = (^{87}\text{Sr}/^{86}\text{Sr})_0 + (^{87}\text{Rb}/^{86}\text{Sr})_t [\exp(\lambda t) - 1]$$

In this equation there are two unknowns: the age t and the isotopic composition $(^{87}\text{Sr}/^{86}\text{Sr})_0$ at initial time. Using several minerals from the same rock or several rocks having the same age t , the two unknowns can be determined. This equation is often displayed graphically as a linear relation referred to as an “isochron” and expressed as $y = ax + b$, with the slope a giving the age of the rock ($a = e^{\lambda t} - 1$) and b the isotopic composition of the melt at the time of its isotopic homogenization or $b = (^{87}\text{Sr}/^{86}\text{Sr})_0$.

It should be stressed that the two fundamental “assumptions” of radiochronology – i.e., that the samples dated have the same age and that the system was isotopically homogeneous at some time in the past – are tested through an isochron diagram; if they fail, the linear relation $y = ax + b$ does not hold.

Relative ages are based on the same principles but the parent isotope has long disappeared. Similarly an isochron can be written using the stable isotopes to normalize the concentration. An important example is ^{26}Al ($T_{1/2} = 0.7$ Ma) which decays into stable ^{26}Mg . Normalizing to the other

stable isotopes of magnesium (^{24}Mg), the isochron equation follows:

$$^{26}\text{Mg}/^{24}\text{Mg} = (^{26}\text{Mg}/^{24}\text{Mg})_0 + (^{26}\text{Al}/^{24}\text{Mg})_0$$

Using the stable isotope of aluminum (^{27}Al), the isochron equation can be rewritten as

$$\begin{aligned} ^{26}\text{Mg}/^{24}\text{Mg} &= (^{26}\text{Mg}/^{24}\text{Mg})_0 + (^{26}\text{Al}/^{27}\text{Al})_0 \\ &\quad \times (^{27}\text{Al}/^{24}\text{Mg}) \end{aligned}$$

For systems formed at the same time with homogeneous Mg isotope compositions, i.e., same $(^{26}\text{Mg}/^{24}\text{Mg})_0$, this equation represents a straight line in a plot of $^{26}\text{Mg}/^{24}\text{Mg}$ vs $^{27}\text{Al}/^{24}\text{Mg}$ (all values measured today). In a continuously homogenized gas that condensed Al-bearing phases, the $^{26}\text{Al}/^{27}\text{Al}$ ratio depends on time and decays by a factor of 2 every 0.7 Ma. Thus, two samples formed at two different times will have a different $(^{26}\text{Al}/^{27}\text{Al})_0$, i.e., a different slope in the isochron diagram. The time Δt elapsed between these two samples is given by $(^{26}\text{Al}/^{27}\text{Al})_{0,1} / (^{26}\text{Al}/^{27}\text{Al})_{0,2} = \exp(-\lambda \Delta t)$. Theoretically a relative chronology can be established for several samples, provided they originated from the same reservoir with homogeneous $^{26}\text{Al}/^{27}\text{Al}$. This point can be tested by plotting Δt vs $(^{26}\text{Mg}/^{24}\text{Mg})_0$: in an infinite reservoir of homogeneous gas, such as the solar nebula, $(^{26}\text{Mg}/^{24}\text{Mg})_0$ should increase with Δt (see equation above) and its rate of change should reflect the $^{26}\text{Al}/^{27}\text{Al}$ of the reservoir. Recent observations on meteorites attest that the Solar System $^{26}\text{Al}/^{27}\text{Al}$ was indeed homogeneous.

In the last 40 years, evidence for the presence of many extinct radioisotopes has been found in meteorites (parent/daughter nuclides): $^7\text{Be}/^9\text{Be}$ ($T_{1/2} = 53$ days), $^{41}\text{Ca}/^{40}\text{Ca}$ ($T_{1/2} = 0.1$ Ma), $^{26}\text{Al}/^{27}\text{Al}$ ($T_{1/2} = 0.7$ Ma), $^{60}\text{Fe}/^{56}\text{Fe}$ ($T_{1/2} = 2.6$ Ma), $^{10}\text{Be}/^9\text{Be}$ ($T_{1/2} = 1.5$ Ma), $^{53}\text{Mn}/^{55}\text{Mn}$ ($T_{1/2} = 3.7$ Ma), $^{107}\text{Pd}/^{108}\text{Pd}$ ($T_{1/2} = 6.5$ Ma), $^{182}\text{Hf}/^{180}\text{Hf}$ ($T_{1/2} = 9$ Ma), and $^{129}\text{I}/^{127}\text{I}$ ($T_{1/2} = 15.9$ Ma). Multiple chronometric systems have been studied in meteorites with the hope of establishing a coherent relative chronology, and substantial progress has been achieved. Isotopic

homogeneities of these radioactive systems in the Solar System are still in debate (Chaussidon and Gounelle 2007).

There are several sources of uncertainties on these ages (see ► [geochronology](#)). When minerals are formed at high temperature in a gas of solar composition, the gas is rapidly mixed by turbulence and isotopic compositions are kept constant. As long as the gas, or the liquid in the case of molten material, is homogenized, the radioactive clock is constantly reset and does not keep the time. When the gas condenses or the liquid freezes, exchange is only achieved by molecular diffusion, a process which is extremely temperature dependent. When isotopic homogenization by diffusion stops and the parent and daughter isotopes remain in the same crystallographic location, the system is closed to exchange, the clock starts ticking, and this is the moment in time which will be dated.

The timescales of closure are also determined by the cooling rate, and for terrestrial magmas, figures of 0.01–1 Ma are not uncommon. For slow cooling, different minerals that originated from the same parent melt may exhibit substantial differences in age. Chondrules (cf. ► [Chondrule](#); Zanda 2004), which are spherules constituting the main mass of chondrites, have a radius in the mm range. They probably remained molten only for minutes, and complete isotopic homogenization of the melt may not have been achieved.

In addition to analytical precision on the determination of isotopic ratios, which depends on each particular chronometer, the most often quoted sources of errors in age are (1) the difference of the closure temperature for different isotope systems and (2) the accuracy of experimentally determined decay constants, which is a serious, neutrino-related issue for β -decay schemes.

A textbook example of (1) is the absolute age of phosphates in H ordinary chondrites determined by the uranium-lead chronometer and for which the mineralogy attests to a progressive metamorphism. The phosphates located in meteorites that experienced the higher metamorphic temperature are 60 Ma younger than their low-grade metamorphic counterpart (Göpel et al.

1994). This duration reflects the time elapsed in the planetoid that originally hosted the H chondrites to reach the closure temperature of the U-Pb chronometer: in the deepest regions of the H planetoid, the temperature reached during metamorphism was the highest, the corresponding cooling rate was the slowest, and the closure temperature for apatite was reached latest. The span in ages of H meteorites has thus no significance as far as their accretion time is concerned, but offers important clues about the thermal history of the parent body.

A second source (2) of errors is the difficulty of measuring decay constants for β -radius activity. This problem is usually solved by cross calibration with U-Pb ages.

The Planetary Significance of Radiometric Ages

In order to obtain an isochron, the process of rock and mineral formation must efficiently redistribute the parent and daughter nuclides and induce variations in the parent/daughter ratios. Such a redistribution is controlled by the chemical properties of the minerals hosting the parent and the daughter nuclides. If the accretion of grains takes place at low temperature (typically <400 °C), the slow diffusivity of most chemical elements prevents such a parent/daughter fractionation from taking place in solids, and these solids cannot be easily dated.

Four processes have been identified that cause chemical fractionation. Some of them are related to phase changes: condensation from a gas, melting, and crystallization of minerals from a cooling silicate melt. Others are slow solid-state processes (metamorphism) and mechanical sorting. These four processes characterize four steps of planetary formation; some of them being still active today on Earth (magmatic activity and metamorphism).

Condensation fractionates parent and daughter nuclides between the solid and the gas, and its efficiency depends on the condensation temperature of each element. Refractory elements, such as Al and Ti, tend to form oxides at high temperatures (1400–1800 K), whereas volatile elements such as K, Na, Pb, and S condense into solids at lower temperature (700–1000 °C).

- Crystallization or recrystallization during magmatic activity and metamorphism fractionates parent and daughter nuclides between minerals as a function of temperature, crystallization rate, and geochemical affinity of the parent and daughter for particular minerals. Some elements tend to enter the liquid during melting, while others partition into some minerals at the early stages of the crystallization.
- Mechanical sorting also fractionates parent and daughter isotopes among silicates, sulfide, and metallic phases. Some elements are preferentially fractionated into silicates while others stay in the metallic melt. The formation of a planetary core is an example of this mechanism.

Ascribing an age to a particular process is essentially based on petrographic observations. For example, several carbonaceous meteorites contain calcium-aluminum-rich inclusions (cf. ► **CAIs**) that exhibit geochemical evidence of condensation at high temperature and – for some of them – of reactions with the surrounding volatile-rich matrix. The oldest ages of CAIs are therefore ascribed to their condensation and their younger ages to secondary heating events. Similarly, iron meteorites or basaltic meteorites result obviously from melts, and thus their ages reflect the time of solidification of these melts.

In summary, the significance of isotopic ages relies on hypotheses that may turn be difficult to test rigorously and independently.

The Age of the Solar System

It is generally accepted that the age of the oldest meteorites is a good approximation of the age of the whole Solar System. Two lines of evidence show that this statement is sound: (1) the Earth, the Moon, and most meteorites have approximately the same absolute age, and (2) this age corresponds to the astrophysical age of the Sun. The recent discovery of ^{10}Be in CAIs from carbonaceous meteorites has improved the precision on the genetic relation between the planets and the Sun (McKeegan et al. 2000). The ^{10}Be is a radioisotope produced by nuclear reactions (*spallation* reactions) between energetic solar particles (*solar*

flares) and the circumsolar gas. These particles are emitted from the young Sun in its *T-Tauri phase*, which lasts no more than a few million years after its birth. The half-life of ^{10}Be being 1.5 Ma, the Sun cannot predate the CAIs by more than a few half-lives of ^{10}Be that is a few Ma.

By the same token, since CAIs contain ^{10}Be produced by solar flares, they cannot predate the Sun. Thus, it is firmly established that the minerals later incorporated into the present-day planets were contemporaneous with the Sun within approximately ± 5 Ma.

This argument can be extended to ^7Be , whose half-life is 53 days. Although the occurrence of ^7Li , the decay product of ^7Be , in the reservoir from which CAIs formed is now confidently established (Chaussidon et al. 2006), it is not possible to ascertain if the ^7Be was still alive during the formation of CAIs. This analytical issue is crucial to establish a strict concordance in ages between the planetary material and the Sun.

The existence of CAIs and their mineralogical compositions were predicted thermodynamically before they were actually found. According to these calculations, they represent the first condensates appearing in the solar gas when it cooled. Their absolute ages of crystallization are indeed the oldest of all the Solar System objects. This age is known with a great precision using the combination of the two chronometers $^{235}\text{U}/^{207}\text{Pb}$ and $^{238}\text{U}/^{206}\text{Pb}$ which provide ages known as lead-lead ages. At the current level of the analytical precision, the CAIs range from 4567.2 ± 0.6 Ma (Amelin et al. 2002) to 4568.5 ± 0.5 Ma (Bouvier et al. 2007) and 4568.2 ± 0.3 Ma (Bouvier and Wadhwa 2010). Scaling this age with the relative age of eucrites suggests that, to a first approximation, the formation of solids and protoplanets took place between 4568 and 4559 Ma ago.

Because of their short half-lives, extinct radionuclides have concentrations decreasing rapidly as a function of time and thus offer a way to establish a more precise chronology of the processes that have taken place during this short period of time, i.e., between 4567 and 4559 Ga.

The Chronology of Accretion

A major discovery in the field of short-lived radioactive nuclides was the finding of ^{26}Mg excesses in Allende CAIs that were positively correlated with the $^{27}\text{Al}/^{24}\text{Mg}$ ratio (isochron), demonstrating that the source of the ^{26}Mg excess was the in situ decay of short-lived ^{26}Al nuclide (Lee et al. 1976). Because the abundance of ^{26}Al found in most CAIs ($^{26}\text{Al}/^{27}\text{Al} = 4.5 \times 10^{-5}$) is higher by at least one order of magnitude than that predicted by models of continuous galactic nucleosynthesis, the presence of ^{26}Al in the protosolar disk requires the presence of a “last-minute input.” The debated question of the origin of the ^{26}Al is not discussed here: either it originated from nucleosynthesis in a massive star dying in the vicinity of the nascent Solar System or may have been produced by local irradiation of part of the protosolar disk by high-energy solar cosmic rays.

Recently, in situ analyses at micrometer scale using secondary-ion mass spectrometers (ion probes) and high-precision magnesium isotopic analyses have shown that the Earth, CAIs, and chondrules (the major high-temperature constituent of chondrites) formed from a reservoir in which the Al/Mg (parent/daughter) ratio and the $^{26}\text{Mg}/^{24}\text{Mg}$ isotopic ratio were homogeneously distributed across the solar nebula. At the current level of analytical precision, this homogeneity allows ^{26}Al to be used as a quite precise chronometer. In this context, high-precision ^{26}Al isochrons for chondrules reveal distinct chondrule melting events taking place between ~ 1.2 and ~ 4 Ma after CAIs, with formation peaks at around ~ 1.5 and ~ 3 Ma.

The mineralogical, textural, and chemical characteristics of chondrules indicate that these objects formed during brief and incomplete melting events of solid precursors (Hewins et al. 2005) and that they subsequently went through strong gas-melt interactions. It is not clear whether this gas was the background [protosolar nebula](#) medium or resulted from the continuous evaporation of solids at high temperature. Lead isotopes show that chondrule formation occurred over a few million years ago. For example, chondrules in the CR-chondrite Acfer have an age of 4564.7 ± 0.6 Ma and therefore postdate CAIs by

about 3.8 Ma. Chondrules in two CB chondrites have younger ages of 4562.7 ± 0.9 Ma and are 5.8 Ma younger than CAIs. In general, the time-scales given by lead isotopes are in quite good agreement with those inferred from the ^{26}Al systematics. Many chondrules, however, show no measurable record of ^{26}Al and no sign of metamorphic perturbations: they are therefore probably younger by at least ten half-lives of ^{26}Al , i.e., ≈ 7 Ma.

The problem of the significance of the chondrule ages is further complicated by the presence in Mg-rich chondrules of unequilibrated, likely relict olivines. This is clearly visible with oxygen isotopes. One of the geochemical requirements for obtaining a radiometric age is therefore not fulfilled since, upon its formation, the melt contained isotopically heterogeneous material. So far, however, no ^{26}Al isochron is known that would support a contemporaneous formation of chondrule and CAIs.

The in situ decay of ^{10}Be into ^{10}B was detected in all CAIs in which the distribution of B was not perturbed by metamorphism, alteration, or contamination, all processes that may have strong isotope effects for a trace element like boron present at the sub-ppm level. However, such a variation cannot be a priori interpreted as a chronological signature because a particularly refractory multiple oxide of Ca, Al, Ti, and Mg known as hibonite present in some rare CAIs appears to have formed with a $^{10}\text{Be}/^9\text{Be}$ ratio which is half the ratio of normal CAIs. In a condensation sequence, a refractory mineral such as hibonite should form early with respect to the other minerals from the same CAI. Therefore the $^{10}\text{Be}/^9\text{Be}$ ratio did not record the condensation time of CAIs but some other process. Because of the small number of documented cases, this conclusion should only be considered as a provisional, but it reaffirms the importance of these observations.

Lithium is very depleted in the Sun. The prevalence of irradiation processes forming ^6Li excesses in the protosolar disk, most likely during the T-Tauri phase of the Sun, is supported by the $^7\text{Li}/^6\text{Li}$ ratio of CAIs, which is lower than in chondrites. Values of $^7\text{Li}/^6\text{Li} = 9.20 \pm 0.22$

were observed in one Allende CAI and of 9.9 ± 1.1 in one Axtell CAI and should be compared with the chondritic value of 12.0 ± 0.3 .

The ^{53}Mn - ^{53}Cr extinct radioactivity is particularly useful for the early history of the Solar System. Numerous isochrons $^{53}\text{Cr}/^{52}\text{Cr}$ vs $^{55}\text{Mn}/^{52}\text{Cr}$ have been produced in meteorites. In CAIs, the parent/daughter fractionation (Mn/Cr) is a magmatic process: Mn and Cr are redistributed among various silicates and metal during melting. Therefore a $^{53}\text{Mn}/^{55}\text{Mn}$ age stands for the age of condensation provided that the post-formation heating events were short. As for ^{26}Al , this last point can be supported by petrological observations. On average, the $^{53}\text{Mn}/^{55}\text{Mn}$ ratio is $2.8 \pm 0.3 \times 10^{-5}$ in CAIs, while chondrules and whole-rock chondrites give a $^{53}\text{Mn}/^{55}\text{Mn}$ ratio of $9.5 \pm 3.0 \times 10^{-6}$. The estimated age difference between CAIs and chondrites ranges between 3.7 and 10.8 Ma. This result is consistent with those obtained from ^{26}Al , although noticeable discrepancies of about ± 2 Ma still exist.

Among the various short-lived radioactive nuclides, ^{60}Fe ($T_{1/2} = 2.62$ Ma decaying in ^{60}Ni) is the only isotope that cannot be produced in the Solar System and must result from explosive nucleosynthesis in distant stars. Evidence of ^{60}Fe occurrence has been found in FeS (troilite) and in magnetite from several ordinary chondrites (Mostéfaoui et al. 2004). The highest $^{60}\text{Fe}/^{56}\text{Fe}$ ratio measured so far is $0.92 \pm 0.24 \times 10^{-6}$. Somewhat lower $^{60}\text{Fe}/^{56}\text{Fe}$ ratios (2.2 and 3.7×10^{-7}) have been found in chondrules. Again, the issue of ^{60}Fe initial abundance and distribution are the subject of ongoing research.

The Chronology of Planet-Forming Processes

Mounting evidence shows that small planetoids accreted and differentiated very early around the Sun, more or less contemporaneously with the formation of CAIs, and thus earlier than chondrites. Recent models of runaway growth show that asteroids can form in a few times 10^4 to less than 10^6 years, but, until very recently, very little isotopic data from meteorites would allow us to constrain such short timescales.

Among the first evidence for an early differentiation of a meteoritic parent body was the finding

of ^{26}Mg excesses in plagioclase crystals from a magmatic (melted) meteorite (the eucrite Piplia Kalan; Srinivasan et al. 1999). A $^{26}\text{Al}/^{27}\text{Al}$ ratio of $7.5 \pm 0.9 \times 10^{-7}$ was inferred from these data at the time of the crystallization of these plagioclases from melts produced during the melting and differentiation of the eucrite parent body, possibly the asteroid $\blacktriangleright$ Vesta. This result implies that differentiation took place very early, some 4.6 Ma after the crystallization of CAIs. Several other similar results were found showing that the differentiation of the planetoids starts as early as ≈ 2.5 Ma after the condensation of the CAIs. The time required for the radioactive elements ^{26}Al and ^{60}Fe to produce enough heat to melt a thousand-kilometer-size asteroid has been estimated 1.8 Ma. This time represents the minimum duration taken by the planetoid to melt after its formation. Accordingly, the accretion age of these differentiated meteorites should postdate the CAI by only $2.5 - 1.8 = 0.7$ Ma.

The extinct radioactivity of ^{53}Mn has also been used to establish a detailed chronology of the differentiation. Igneous meteorites (eucrites) define a single isochron with a slope indicative of a $^{53}\text{Mn}/^{55}\text{Mn}$ ratio of $4.7 \pm 0.5 \times 10^{-6}$. This whole-rock isochron dates fractionation of Mn from Cr, which is thought to represent the isolation of the material that formed the eucrites prior to their melting. The corresponding time elapsed between the formation of the CAIs and the formation of the eucrite parent body before its differentiation is ≈ 11 Ma. Alternatively, if different minerals from a same sample are analyzed separately, the isochrons of each meteorite, the duration of the differentiation process increases to 18 Ma.

Among meteorites, iron meteorites are pure metallic bodies. They likely result from melting of asteroids followed by a gravitational segregation of the metallic and silicate melts. The metal segregates and eventually crystallizes to form the planetary cores. Debris of such cores produced by collisions among asteroids or by tidal effects in the asteroid belt are now sampled as iron meteorites. Because reducing conditions are prevalent at high temperatures, early melting of asteroids must have resulted in metal-silicate differentiation. ^{182}Hf decays to ^{182}W with a half-life of 8.9 Ma,

and the ^{182}Hf - ^{182}W system is a suitable chronometer to date core segregation: W fractionates into the metal and Hf into the silicate mantle. The radiogenic ^{182}W excesses measured in CAIs are used to determine that, at the time of formation of CAIs, the $^{182}\text{Hf}/^{180}\text{Hf}$ ratio in the protosolar nebula was $1.07 \pm 0.10 \times 10^{-4}$ and tungsten was depleted in ^{182}W by $\approx 0.35\%$ with respect to the Earth. Surprisingly, the ^{182}Hf - ^{182}W ages of the iron meteorites are indistinguishable from those of CAIs (Kleine et al. 2005), which, taking uncertainties into account, requires that the metal-silicate differentiation took place on the parent body of magmatic irons no later than ≈ 1 Ma after CAIs. Again a picture in which small planetoids accrete very early in the protosolar disk emerges from this chronometer.

If asteroids indeed formed early – say between 0.1 and 1 Ma – most of them experienced high collision rates during the runaway growth period. Because chondrules seem, on average, to be younger than CAIs by up to a few Ma, their precursors might have incorporated fragments of the early

accreted and differentiated asteroids. Such fragments were isolated recently in chondrules from the CV carbonaceous chondrite Vigarano. Oxygen isotopes show that these chondrules contain relict textures that are most likely accounted for by small fragments of olivine-rich differentiated planetoids. The different aspects of the chronology of the Solar System formation discussed in this text are summarized (Fig. 1).

Future Directions

The age of the oldest known solids of the Solar System is now known to be within ± 0.3 Ma at 4.5682. Condensation and accretion of all solid material in the Solar System took place within a few million years of this age. The presence of the in situ decay products of short-lived radioactive nuclides in both undifferentiated and differentiated meteorites demonstrates that, within a few million years or less, grains were condensed and the first planetoids were accreted and then

System Solar Formation, Chronology of, Fig. 1 Ages are reported for chondrules and for differentiated meteorites (eucrites and irons). The absolute age of CAIs is expressed in billions of years (Ga); all other ages are relative to CAIs and expressed in millions of years (Ma). The extinct nuclides used for these relative determinations

are indicated (*dashed error bars* stand for lower limits). Contrary to chondrules that cooled rapidly, for eucrites and irons, it is possible to define an accretion age that predates their complete melting (differentiation). The age of the Sun is indirectly deduced from the presence of live ^{10}Be in CAIs, which is produced by solar flares at its birth

differentiated. Various chronometers provide an overall consistent chronology but show some discrepancies in detail. Several assumptions underlying isotopic chronometry still need validation and should be regarded as pending issues, namely: (1) Was the distribution of the various short-lived radioactive nuclides across the disk homogeneous in time and space? (2) To what extent were the observed short-lived radioactive nuclides' abundances modified by secondary processes either in the solar nebula or on the parent bodies?

Definition

Systems biology is a young scientific discipline within the broader field of cell biology, or biology at large, whose major goal is the study of complex dynamic behaviors in biochemical and interactive networks, through the acquisition of quantitative experimental data and the complementary aid of theoretical modeling and computational tools. It is considered a more comprehensive or holistic approach than those traditionally taken in biological and biomedical research to deal with metabolic processes, regulatory networks, and adaptive cellular responses. For general references on this topic, see (Kitano 2002; Westerhoff and Palsson 2004; Boogerd et al. 2007; Camacho and Collins 2009; Klipp et al. 2009; Hübner et al. 2011).

History

Over the last century, a number of scientists and philosophers pointed out the necessity of adopting a *systems* perspective in order to make significant scientific progress, especially with regard to the challenge of biological complexity (de la Escosura et al. 2015). Von Bertalanffy was one of those pioneers, putting forward a “theory of systems” already in the 1950s and 1960s (von Bertalanffy 1950). However, he did not provide a concrete methodological framework to develop such a research program in practice, probably because the required technological advances were not available at that time yet. In addition to those early insights, various disciplines seeded the scientific soil with ideas that contributed to the later foundation of systems biology, like cybernetics and control theory, nonequilibrium thermodynamics, or the mathematical modeling of enzyme kinetics and population growth, among others. The actual term “systems biology” was coined in this context by Mesarovic (1968), followed by other relevant theoretical developments for the field, such as metabolic control analysis, biochemical systems theory, and the first stochastic simulations of complex reaction dynamics. However, the golden age of systems biology came with

the advent of genomics, proteomics, and metabolomics (i.e., the “omics” revolution) in the late 1990s, which allowed gathering massive amounts of biochemical data. With the main objective of providing an adequate interpretation of those data and contributing to integrate knowledge from different levels of description of the living phenomena (in particular, from the biomolecular and cellular levels), the field of systems biology has been growing exponentially since 2000 (Hübner et al. 2011).

Overview

Systems biology, rather than a full change of paradigm, represents an important move to find a new balance in the natural sciences, a redistribution of weights in the production of biological knowledge. Oversimplifying history, during the second part of the twentieth century, the focus of biology was on the discovery of the molecular bases that could account for the complex properties and behavior of living organisms. Then, with the increased power of molecular biology’s data extraction techniques (the “omics” era), the need to find criteria to interpret that huge amount of information, together with new explanatory tools to link molecular specificities with global cellular responses, became more manifest. Systems biology was the main response from the community (hand in hand with other emerging research areas, like bioinformatics, synthetic biology, or computational biology) to those new challenges. Essentially, it proposes the combination of experimental and theoretical modeling methodologies to work out possible mappings or connection routes (both “upward” and “downward”) between molecular details and collective dynamic behaviors, with special emphasis on the cellular level – but also below and, potentially, beyond that level.

Some of the topics currently faced by systems biologists include the study of information processing in signaling networks, the inference of mechanistic models for intricate phenotype development, the modeling of metabolic interactions and complex microbiomes, or the understanding of cellular dynamics and regulation. More

recently, systems biology is starting to contribute significantly to the field of biomedicine, as well (e.g., in drug design and development – see Brown and Okuno 2012). It keeps a special relationship with synthetic biology, a field that was founded approximately in the same historical period and may also be instrumental to reveal basic principles of biological organization – in this case, by synthesizing and trying to assemble standardized bio-modules into more complex circuits or networks. Finally, systems biology has served as a source of inspiration for the onset of its sister discipline in chemistry, “systems chemistry,” whose aim is to understand the emergence of biological phenomena from their chemical bases, namely, through the spontaneous self-organization of biomolecular components into protocells and, ultimately, living cells (de la Escosura et al. 2015).

Definition

Systems chemistry is an area of chemistry that seeks insight into complex networks of interacting molecules and their system-level properties. These properties emerge through the collective behavior of the system’s components and cannot be attributed to the individual components acting in isolation. The way in which specific interactions between the components propagate through the system dictates these emergent properties.

History

The term “systems chemistry” was first used in 2005 by von Kiedrowski in a publication (Kindermann et al. 2005) describing the kinetic and computational analysis of a nearly exponential organic replicator. In this paper, von Kiedrowski claims new research “could open a door to a field that may be termed systems chemistry, namely, the design of prespecified dynamic

behaviour.” In the same year, a systems chemistry workshop (Stankiewicz and Eckardt 2006) was held in Venice, Italy where a more detailed definition was given describing systems chemistry as “a new field of chemistry seen as the offspring of prebiotic and supramolecular chemistry on the one hand and theoretical biology and complex systems research on the other.” In 2007, a new EU research network on systems chemistry (COST CM0703; European Cooperation in Science and Technology) was established, which followed a similar line of reasoning. In the context of this COST Action systems chemistry is seen as the bottom-up chemical pendant of systems biology toward synthetic biology. This approach would be made feasible by a joint effort of prebiotic and supramolecular chemistry assisted by computer science from theoretical biology, theoretical chemistry, and complex systems research to tackle dynamic supersystem integration including at least one autocatalytic subsystem. In 2009, the Centre for Systems Chemistry was established at the University of Groningen, Netherlands, and an open access *Journal of Systems Chemistry* (von Kiedrowski et al. 2010) was launched through the Chemistry Central platform now part of the Springer publishing house. The 2007 COST action was followed by Action CM1304 that started in 2013.

Overview

Most chemists have traditionally focused on devising chemical transformations that produce a single, desired compound with given properties selectively. In such approaches, mixtures of compounds are undesired and eliminated with various purification techniques. This situation is no longer the case, since more complex mixtures have become tractable by the development of advanced analytical methods. Today, it is possible to move away from the reductionist approach that inspired most research in chemistry previously and develop methods to study multiple variables simultaneously paving the way for systems chemistry (Ludlow and Otto 2008; Peyralans and Otto 2009; Nitschke 2009; Stoddart 2012). Systems

chemistry defines a new area of chemistry in which a few already well-established branches of chemistry come together. Many systems featured in the area incorporate phenomena under thermodynamic control such as dynamic combinatorial libraries (Li et al. 2013), molecular recognition, and self-assembly. In many cases, it is the combination and fine interplay between these elements that give rise to specific emergent properties sought for in systems chemistry research. While thermodynamically controlled molecular networks are probably easier to study and understand, kinetically controlled networks have greater relevance to biology, as life operates far from equilibrium. Some examples of studied kinetic processes in the scope of systems chemistry include autocatalytic reactions and self-replicating molecules, kinetic self-assembly, self-sorting processes, and oscillating reactions. One of the major questions that systems chemistry sets out to answer (Szostak 2009; Ruiz-Mirazo et al. 2014) is what made the transformation of a complex mixture of molecules on the prebiotic Earth into a living chemical system possible. What most researchers agree upon is that a combination of thermodynamic and kinetic processes as well as an array of auto- and cross-catalytic cycles played a major role in this development. Another aspect of this research is finding out why the particular biochemical building blocks of life that we know today were selected and how some of these biomolecules developed to have specific chirality. Systems chemistry addresses these issues by devising model synthetic systems with properties that could reflect aspects of prebiotic biogenesis. Another topic at the core of systems chemistry is the quest for de novo life. However, life is just one incredibly complex functional molecular system, and many others are conceivable, and what may be achieved with systems chemistry is ultimately only limited by the creativity of the chemist.

T

T Association

Steven W. Stahler
Department of Astronomy, University of
California, Berkeley, CA, USA

Definition

Solar-type stars that are still in the pre-main-sequence phase of evolution are known observationally as ► [T Tauri stars](#). These objects are not seen in isolation but in coherent groups, known as T associations. One example is Taurus-Auriga, about 140 parsecs away. Along with the eponymous T Tauri stars, which are optically visible, the associations also contain more embedded, infrared objects. Indeed, the entire group is contained within a ► [molecular cloud](#). The density of stars is too low for significant mutual gravitational attraction. Rather, the group is maintained by the gravity of the parent cloud.

T Tauri Star

Steven W. Stahler
Department of Astronomy, University of
California, Berkeley, CA, USA

Keywords

Star formation

Definition

T Tauri stars are solar-type objects in the pre-main-sequence phase. They are found in loose groups, located in or near molecular clouds. All T Tauri stars exhibit variability in their light and have strong surface magnetic fields. Some, the classical T Tauri stars, have strong spectral emission lines in their spectra, as well as an infrared and ultraviolet excess. The weak-lined T Tauri stars are lacking in these properties. These differences plausibly reflect the presence or absence of circumstellar accretion disks. In any case, both types are located above the main sequence in the ► [Hertzsprung-Russell \(HR\) diagram](#), confirming their pre-main-sequence status.

Overview

Stars that are too young to fuse hydrogen into helium are said to be in the pre-main-sequence phase of evolution. Lacking a nuclear energy source, these objects contract gravitationally. Contraction drives up the central temperature. Eventually, the temperature is high enough for fusion to begin. The star has now joined the main sequence, the evolutionary phase of our Sun and most other stars we see.

T Tauri stars are pre-main-sequence objects similar to the Sun in mass. They can easily be distinguished from main-sequence stars by their irregular variability and their strong spectral emission lines, particularly the H alpha line at 6563 angstroms (656.3 nm), as well as by the presence of ► [lithium absorption](#). They are found within groups called T associations, which are in or near regions of visual obscuration. Such patchy obscuration is caused by molecular clouds, confirming the youthful status of this class of stars.

We may also gauge their evolutionary status in a more quantitative manner. Once the surface temperature and total luminosity of a star are measured, the object may be plotted in the HR diagram. When this exercise is done for any T association, the representative points fall below the stellar ► [birthline](#) but above the main sequence. Moreover, their positions within the diagram allow one to assess the stars' ages. This technique gives T Tauri stars ages of a few million years.

There are two broad classes of T Tauri stars – classical and weak lined. Both are located above the main sequence in the HR diagram. Only classical stars, however, exhibit strong emission lines. They also have infrared and ultraviolet excesses, as gauged from their spectral energy distributions. Weak-lined stars, as the name implies, lack the strong emission lines, as well as infrared and ultraviolet excess. Both types of stars are variables, and both have strong magnetic fields.

These differences in part reflect the presence or absence of circumstellar disks. Such disks are present in classical T Tauri stars. The infrared excess arises from heated dust in the disk, while the ultraviolet may originate from disk matter crashing onto the stellar surface. Apparently, the

disks are absent in weak-lined stars, although these objects have similar ages. As pre-main-sequence stars further evolve, their infrared and ultraviolet excess and temporal variability fade away. There should be large numbers of relatively nearby post-T Tauri stars, although only relatively few have so far been observed.

TACK, Archaea

Ricardo Amils
Departamento de Biología Molecular, Centro de Biología Molecular Severo Ochoa, Universidad Autónoma de Madrid, Madrid, Spain

Definition

TACK is the acronym for a group of archaea originated from the names of the first identified

phyla (Thaumarchaeota, Aigarchaeota, Crenarchaeota, and Korarchaeota). They have been identified in diverse extreme environments like those at high temperature (thermophiles), low temperature (psychrophiles), and low pH (acidophiles). Most members of this group are anaerobic. Crenarchaeota are the best known members of this group; together with the Euryarchaeota, these were the first two phyla described for the archaeal domain. Due to their metabolic relationship with sulfur compounds, they were also known as “sulfo-bacteria.” The best characterized hyperthermophilic archaea belong to the Crenarchaeota phylum (*Sulfolobus acidocaldarius*, *Pyrodictium occultum*, *Pyrolobus fumarii*, *Ignicoccus islandicus*). Korarchaeota was the third historical phylum described for Archaea and most of its members were detected in hydrothermal environments.

Taq Polymerase

Ricardo Amils

Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Synonyms

[Heat-stable DNA polymerase](#)

Definition

Taq polymerase denotes the heat-stable DNA polymerase extracted from the thermophilic bacterium *Thermus aquaticus*. It is used to automate the repetitive steps in the ► [polymerase chain reaction](#) (PCR) technique, an extremely important method of amplifying specific DNA sequences. The polymerase chain reaction can multiply DNA molecules up to a billion-fold in the test tube, yielding large amounts of specific genes for their use in multiple applications. The steps in PCR amplification are the following: DNA incubation with an excess of specific primers of the selected gene, the DNA polymerase extends the primers using the target strands as templates, after incubation the mixture is heated to separate the DNA strands and cooled to allow primers to hybridize with complementary regions of the newly synthesized DNA and, finally, the operation is repeated several times. The introduction of a thermophilic DNA polymerase avoids the denaturation of the enzyme during the heating step required to separate the newly synthesized strands, thus simplifying the methodology while increasing its efficiency.

Tautomer

Henderson James Cleaves
Earth-Life Science Institute (ELSI), Tokyo
Institute of Technology, Tokyo, Japan
Blue Marble Space Institute of Science,
Washington, DC, USA
Center for Chemical Evolution, Georgia Institute
of Technology, Atlanta, GA, USA

Definition

A tautomer is a constitutional isomer of a compound, most usually an organic compound, that has a low energetic barrier to interconversion to another isomeric state (which is another tautomer of the same molecule), a process termed tautomerization. Tautomerization may result in the migration of a proton, accompanied by the change of location of a single bond and an adjacent double bond. Due to the low energetic barrier to interconversion and consequent rapid interconversion of tautomeric forms, tautomers are generally considered to be the same chemical compound, though they have different formal bonding geometries.

Tautomerization produces an equilibrium mixture of possible tautomers. The final ratio depends on factors including temperature, solvent, and pH, as well as the intrinsic stability of the tautomers. Prototropy is a special form of tautomerism caused by the relocation of a proton in a molecule. Prototropy is a form of acid-base behavior.

Keto-enol and imine-enamine tautomers are especially important in the process of mutation

in nucleic acid copying. For example, the nitrogen heterocyclic moieties of nucleotides can exist in various tautomeric equilibria, some of which are able to form mismatched base pairs with non-canonical complements.

Taxonomy

Ramon Rosselló-Móra
IMEDEA (CSIC-UIB), Mallorca, Spain

Keywords

Classification · Hierarchy · Systematics

Synonyms

[Classification](#)

Definition

Taxonomy (from Greek *taxis* [order or arrangement] and *nomos* [law or science]) is the scientific discipline that deals with the classification of the living organisms.

Overview

Taxonomy pursues the generation of a classification system that is operative and predictive with the ultimate goal of identifying the patterns of recurrence (► [species](#)) that can be observed in nature. However, the word “taxonomy” is often used as a synonym for “classification,” and both terms indicate the hierarchical system that organizes biological diversity. Taxonomy is an

essential discipline of the biological sciences because it provides a framework that facilitates the scientific community's understanding and knowledge exchange. The main basis of taxonomic classification is the category of "species" that is considered as the unique entity. Different taxonomies tailor their species circumscriptions with different criteria depending on their ability to reveal genetic, phenotypic, and ecologic particularities. Thus, such units are not always comparable. However, higher-rank categories (from genus to phylum) are considered abstract entities and thus comparable among the different taxonomies. The main success of taxonomy will be to achieve a classification that reflects the natural genealogical and evolutionary relationships among living (and fossil) organisms.

It is perhaps one of the oldest biological sciences, having been in existence for at least 2400 years, since Aristotle devised the first hierarchy based on creationist and essentialist tenets. Linnaeus established the first serious taxonomy in the eighteenth century when he created the binomial system of nomenclature (genus and specific epithets) for plants, as well as the first hierarchical system based on five taxonomic ranks (kingdom, class, order, genus, and species). Later, in the middle of the twentieth century, Mayr and Simpson enlarged the hierarchical system in about 19 different taxonomic ranks as a result of an enormous increase of classifications and the difficulties in fitting them into the five-rank system. One of the major drawbacks of the current view on taxonomy is that scientists take for granted that the whole of biological diversity, including prokaryotes and eukaryotes from any source, can be organized by following a single hierarchical model of categories, equally ranked for any kind of organism, which is a tendency called "monism" by philosophers. However, some scientists advocate for the allowance as many parallel taxonomies as possible, following a tendency called "pluralism" by philosophers, as the only solution to the so-called species problem.

The success of taxonomy as a science will be the achievement of a classification system that is operative and predictive (i.e., the identification of an individual belonging to a given taxon will be

accompanied by the prediction of genetic, phenotypic, or ecologic traits) and reflects the natural relationships among the classified organisms.

Telescope

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Keywords

Image formation · Mirror · Optics · Radio telescope

Definition

A telescope is an instrument used to study remote objects in the universe. It is able to collect on a large surface the ► [electromagnetic radiation](#) (light) emitted by those objects when it reaches Earth. Originally designed for visible light, telescopes have now been developed for all other types of electromagnetic waves, from gamma rays to radio waves.

Overview

Geometrical optics provides the first approximation in designing a telescope. Whatever the total number of mirrors or lenses used, the telescope has a first optical element of large dimension which defines the capacity of energy collection and forms a first image. This first element (lens or primary mirror) is generally followed by other optical elements (secondary, tertiary) whose purpose is to change the magnification and improve the image quality. At the end of the chain, the focal plane of the telescope is found, where the light is concentrated and the image is formed to be used by dedicated systems for analysis (camera, spectrometers, polarimeters, etc.).

The main parameters for characterizing a telescope are:

- (a) The focal configuration. Figure 1 depicts the most usual ones. The Cassegrain configuration where the beam crosses the primary mirror through a central hole is one of the most current. Note that a single telescope may have several foci, the transition from one to another being done by simply switching a secondary or tertiary mirror. The advantage is to have different instrumentations available and to switch from one to another with no loss of time.
- (b) The scale of the image at each focal plane, usually given in mm per arcsec. This scale should be adapted to the pixel size of the analysis systems.
- (c) The numerical aperture of the beam, given by the ratio f/D , i.e., the equivalent focal length to the diameter of the primary mirror.
- (d) The field, which is the region of the focal plane in which both the image quality and the uniformity of illumination remain acceptable.
- (e) The quality of the image. It is measured by the angular diameter of the circle in which a significant fraction (e.g., 50% or 80%) of the energy of a point object is focused.

Telescope, Fig. 1 The different possible focal configurations found in a telescope

Telescopes operating in the visible are the oldest imaging instruments used in astronomy. The increase in diameter was made in stages, depending on advances in materials and technologies: after refractors, whose role was virtually extinct in the twentieth century, the first half of that century saw the appearance of instruments with mirror diameters of 5–6 m, followed by mirrors up to 10 m in the second half. By the years 2020–2030, there is little doubt that instruments from 30 to 50 m in diameter will come into operation. Their extension to the near and medium infrared was made in the 1970s, with the availability of sensitive detectors and of sites of excellent quality that allowed good atmospheric transmission in a few spectral windows. Some recent developments have allowed astronomers to go beyond the apparent limits set by the difficulty of access to space and by image degradation due to atmospheric turbulence. During the late

1970s, it was thought unlikely to continue construction of telescopes on Earth with a diameter larger than 5–6 m. This view quickly evolved for a set of reasons:

- The technological limitations in the construction of very large mirrors have been overcome, thanks to the emergence of new materials (ceramics), the advent of active control of thin mirrors leading to substantial reductions of weight, and by making segmented mirror surfaces.
- Methods of correction of atmospheric turbulence have emerged in the late 1980s and (► [Adaptive Optics](#)) preceded by numerical methods for post-correction of images (speckle interferometry) in the 1970s; breaking the limit previously imposed by turbulence (atmospheric “seeing”), they allowed astronomers to actually benefit from the

theoretical gain of angular resolution proportional to the diameter D of the telescope (see ► [Diffraction](#)).

Telescopes were traditionally installed on an equatorial mount with one axis parallel to Earth's rotation axis, which allowed a simple motion about that axis to compensate for the diurnal motion. These are now discontinued, for reasons of space and lightness and therefore of cost, in favor of so-called altazimuth mounts, where the diurnal motion compensation operating on two axes is driven by a computer.

Telescopes for reception in the radio domain are called radio telescopes or antennas. These telescopes are usually made of a very large primary mirror (tens or hundreds of meters), generally parabolic, whose precision of surface is fixed by the wavelength of use. The surface may even be made of metallic mesh or panels. The growing importance of the submillimeter domain leads to the building of quality mirrors, at the borderline of optical instrumentation. The receiver, either based on heterodyne principles for spectroscopy or a bolometer for measuring continuum emission, is either placed directly at the primary focus or at a secondary Cassegrain focus. Multi-pixel array receivers are now becoming common. On Earth, the telescope is usually carried by an altazimuth mount and follows the source in its diurnal motion. At these wavelengths, the sky is practically the same between day and night so that these instruments can operate continuously. The robustness of their mirror allows them to be built in the open air, without a dome, which reduces the cost.

At high energy the term telescope is still used, but the instruments are very different from a conventional telescope. In the X-ray domain, grazing Wolter telescopes are used: they are composed of ring-shaped mirrors made of heavy metals that are able to reflect the rays hitting the surface at a very large incidence close to 90° . The mirrors are usually a section of a rotated parabola followed by a hyperbola, many rings (typically 30) being nested to reach a reasonable projected surface, and feeding a common focus.

For gamma-ray telescopes, there is no longer an attempt to concentrate the light; the detector defines the collecting surface, and a coded aperture mask made of titanium is put at a certain distance from the detector: the patterns of the shadows the mask creates when illuminated by different sources can be reconstructed to form an image. The angular resolution of this solution is rather poor (typically 1°).

Teloempathy

Octavio A. Chon-Torres
Programa de Estudios Generales, Universidad de Lima, Lima, Perú

Definition

According to Cockell (2005a, b) and Cockell (2011) teloempathy is the ability to recognize

the interests of other extraterrestrial living things, in the eventual case that their discovery is confirmed. For example, on Mars, if any form of microbial life were confirmed there, they would have no way of claiming their own rights, so we, in an act of empathy that is not limited to terrestrial life forms, can watch over their integrity and avoid putting them at risk. Teloempathy would represent a way of acting and seeing things that moves us from ethical biogeocentrism (Chela-Flores 2001, 2009; Aretxaga 2004) toward a perspective that brings us closer to astrobiocentrism (Chon-Torres 2020, 2021).

Template

Carlos Briones

Centro de Astrobiología (CSIC/INTA), Consejo Superior de Investigaciones Científicas, Madrid, Spain

Definition

In molecular biology, a template is a molecule that carries genetic information and can be used to make copies of itself. The template molecule is single stranded (ss) DNA in DNA replication – also known as DNA-dependent DNA polymerization, catalyzed by DNA polymerase enzymes – and in transcription – DNA-dependent RNA polymerization, catalyzed by RNA polymerases. In viruses with an RNA genome, ssRNA templates can be used in either RNA replication – RNA-dependent RNA polymerization, catalyzed by viral-encoded RNA polymerases – or reverse transcription – RNA-dependent DNA polymerization, catalyzed by reverse transcriptases in retroviruses. In all cases, the template molecule directs the synthesis of its complementary molecule. In the origin of life field, template-independent and template-dependent – both nonenzymatic and enzymatic – nucleic acid polymerization processes are studied. Additionally, ssRNA template molecules – in the form of mRNA – are used by ribosomes to translate their nucleotide sequences into the amino acid sequences of the encoded proteins.

replication](#)

Definition

The concept of template-directed polymerization refers to a chemical reaction in which a polymer is synthesized from monomeric units using a template, i.e., another polymer molecule, as a reaction directing molecule. In nucleic acid replication, the template sequence (i.e., the order of nucleobases in the template) determines the nucleobase sequence of the polymer product because the monomer units, the ► [nucleotides](#), assemble onto the template due to a molecular recognition based on Watson-Crick base pairing with the template before being covalently linked together. Stacking between monomer nucleobases further stabilizes monomer-template complexes. Short oligomers are sometimes viewed as “monomeric” units in template-directed ligations.

History

The nature of primitive metabolism that allowed for nonenzymatic replication of informational polymers is unknown. Many hypotheses regarding its nature have been put forward on the basis of comparisons with contemporary cellular life. Although it was obvious that a simpler system must have preceded today’s cellular biology, the interdependence of proteins and nucleic acids for their replication has long remained a profound puzzle (often depicted as the “chicken and egg” paradox). In fact, a “satisfactory” answer to this dilemma could not be envisioned until the ► [RNA world](#) concept was first hypothesized in the 1960s by C. Woese, F. H. C. Crick, and L. E. Orgel, among others, and later named as such by W. Gilbert. These authors postulated an autonomous RNA-based “organism” in which RNA molecules could perform catalytic functions presently carried out by proteins while also acting as a repository of genetic information. Although the RNA world seems to be ineluctable at some point during the emergence of cellular life from inanimate matter, it is not clear whether it represented the first system during the evolution of life. In fact, the evidence at hand still leaves open questions about the origins and “biochemistry” of the RNA world. A successful implementation of this hypothesis, however, presupposes efficient, nonenzymatic information transfer and amplification based on the template-directed polymerization of nucleotide monomers.

Overview

Two separate issues impact the ability of nucleic acid monomers to ligate during template-directed polymerization: (1) the stability of the hybridized system, which improves as the length of the newly synthesized, complementary chain increases, and (2) the likelihood that the neighboring monomers to be ligated align themselves (i.e., stack) to facilitate polymerization. In addition, phosphodiester bond formation requires energy input, which is often provided by activated monomers, e.g.,

► [nucleoside phosphoimidazolides](#), whose availability on the early Earth is questionable.

In homogeneous (bulk) aqueous solutions, efficient nonenzymatic, template-directed polymerization of activated purines on their complementary pyrimidine strands has been observed. However, activated pyrimidines, in particular uridine ► [ribonucleotides](#), have never been efficiently incorporated into an RNA strand, most likely because of poor stacking interactions due to their high hydrophilicity. In fact, the presence of two consecutive adenosine residues on a template completely inhibits polymerization, as this implies two stacked uridine nucleotides in the complementary strand. Furthermore, it has also been experimentally observed for guanosine monomers that a heteropolymeric template must contain at least 60% of cytidine residues for efficient “replication” to occur. Although the complementary strand can be produced in this case, the cytosine-enriched template itself will not be reproduced, as its own template would contain $\geq 60\%$ G-residues and hence $\leq 40\%$ C-residues. Thus, no nonenzymatic, template-directed amplification of RNA from monomers can take place.

To solve the issues, which appear to prohibit two-way template-directed polymerization as noted above, two main approaches have been proposed: either to create microenvironments amenable to polymerization or to improve the intrinsic properties of the monomers. Among the proposed environments, montmorillonite clays, lipid-bilayer matrices, and eutectic phases in water ice have been investigated. Derivatives of ribonucleotides with higher intrinsic reactivity, in particular 5' or 3' amino-substituted ribonucleotides, or the effects of molecular helpers or “midwives”, such as large heterocycles, that increase stacking between monomers have also been studied. Although these two pathways may not be directly relevant to the emergence of an information system on the early Earth, they have already delivered promising results that suggest that template-directed polymerization of RNAs and RNA analogs may be possible.

Terminal Sterilization

J. Andy Spry
SETI Institute, Mountain View, CA, USA

Definition

In planetary protection, terminal sterilization is a process for ► [Bioburden](#) reduction that is

performed on the entire spacecraft system after assembly is completed. For example, the ► [Viking](#) spacecraft in the 1970s were baked at 111.7 °C for 50 h at the end of the assembly phase (as opposed to sterilization of subsystems being sterilized before assembly). Terminal sterilization reduces the risk of recontamination in the assembly and test process. These are, to date, the only interplanetary spacecraft subjected to such a terminal sterilization process.

Terrestrial Analog

Felipe Gomez
Centro de Astrobiología (CSIC/INTA), Instituto
Nacional de Técnica Aeroespacial, Madrid, Spain

Keywords

Europa analogues · Extreme environments ·
Extremophiles · Mars analogues

Synonyms

[Analog sites](#)

Definition

A terrestrial analogue is a field site which bears an analogy or similarity in some way to conditions on other planetary bodies of the solar system; e.g., analogues to ► [Mars](#) or Jupiter's moon ► [Europa](#) are the Atacama Desert and Lake Vostok, respectively. Similarities can be related with

physicochemical conditions, such as dryness, low water activity, mineralogy, or chemical composition of the ► [environment](#). Low water activity would be the case for the Atacama Desert's similarity with the Mars surface, while a subsurface ocean under an ice layer applies approximately in the case of Lake Vostok and the moon Europa.

Overview

Solar system exploration takes advantage of some peculiar Earth sites which can serve as field facilities or Earth references. These sites are called Earth analogues and can be used as reference because they have particular similarities or characteristics that resemble those found on an extra-terrestrial planetary body. Normally these places correspond to extreme environments. Terrestrial analogues can share geological similarities with some planetary bodies (e.g., geochemical similarities between ► [Rio Tinto](#) in southwest Spain and Meridiani Planum location on Mars where the NASA Opportunity rover is located).

Terrestrial analogues play at least three important roles in planetary science:

1. As field sites on Earth where one may learn about planetary processes, e.g., geological information to be compared with that reported from space missions, mineralogical databases for comparison with spectral data from Mars orbiters, and comprehension of the processes that originated some particular materials or rocks in particular environments (e.g., lunar igneous rocks) in comparison with similar materials on terrestrial analogues (Drever et al. 1972).
2. To study life's survival limits as a means toward its comprehension and definition. From desert low water availability and high temperature to cold environments in the polar regions, microbial ► [life](#) has been identified that survives in those extreme conditions. As an extrapolation, the evaluation of the habitability of an extraterrestrial planetary body and the search for life out of the planet Earth (one of the main goals of astrobiology and the

national space agencies) could be verified through the research of life in extreme environments.

3. Validation of new technology, protocols, and tools for space missions.

Some Mars and Europa Terrestrial Analogues

An extreme environment can be described as a terrestrial analogue of Mars or Europa based on similarities in geology, mineralogy, chemistry of the system, temperature, salinity, or dryness. Based on these parameters, we consider as analogues the dry valleys in Antarctica; subglacial lakes in Antarctica; Svalbard in Norway, all of them with low temperature and low-water-availability environments; Rio Tinto in Spain as a Martian analogue due to its complex chemistry and mineralogy; and the Atacama Desert as a Martian analogue because it is one of the driest place on Earth (Figs. 1 and 2).

Dry valleys in Antarctica are well-recognized Mars analogues due to the very low temperature and low moisture availability in the environment. These environments have been well used to study very extreme and simple ► [ecosystems](#) with a strong interaction between biology and geological formations. The area is constituted by a ridge crest network with valleys in between, with dimensions of 5–10 km in width and 20–50 km in length. Most of them have neither glaciers on their heads nor snowfall over the year. The temperature in the salty valleys on western Antarctica rarely gets above -30°C , and annual rainfall is less than 10 mm, resembling those conditions found on some locations on the surface of Mars. Well-characterized basalt geological formations constitutive of permanent permafrost areas, with surfaces frozen over all or most of the year, resemble those typically basalt substrates on Mars. Another important similarity with Martian permafrost areas that can be used for studies of geological processes is the formation of polygonal terrains and other permafrost patterns with amazing morphological similarities. The ice polygons of the Antarctica valleys have diameters of 20–30 m with associated frost wedges increasing in thickness with each annual cycle. From narrow cracks in the ground, the wedge width increases

**Terrestrial Analog,**

Fig. 2 Atacama Desert in Chile is considered the driest place on Earth

progressively with polygonal permafrost pattern formation as final result.

More than 20 years ago, scientists reported that some organisms were able to colonize particular locations such as the interior of sandstone deposits, the interior of porous rocks, and surface pavements in the Antarctic Dry Valleys. In spite of the harsh and restrictive conditions, algae, fungi, and bacteria were identified in the Antarctic Dry Valleys. In the 1980s, other niches were identified for algae and bacteria. Long-lived algal mats were located submerged under lake ice crust. Bacteria

were also identified in hot volcanic fumaroles of Mount Erebus.

But not only these harsh and restrictive conditions made Antarctica valleys interesting from an astrobiological point of view. The presence of well-protected subsurface ecosystems such as permafrost areas or lakes with frozen surface most of the year made these environments of special interest. Several lakes with subsurface-protected environments are located not only in the valleys but in other Antarctic areas. Some ice landforms at McMurdo Dry Valleys' glaciers have been

suggested as terrestrial analogues for the sublimation behavior of Martian icecaps, where surface melting is absent, but other important processes are key elements for unusual ice feature formations such as dark spirals and circular pits.

Some of the lakes located on the dry valleys are over 20-m deep and have 2-m-thick ice covers. Some organisms living on and in the ice have been reported to be relevant for astrobiology models for Jupiter's moon Europa. These lakes are good venues for technology exploration capacity development in lake-bottom exploration such as SCUBA divers, including core sampling of sediments. These technological developments can be implemented for later space missions in similar environments on other planets or moons.

Also with important implications for Europa moon astrobiological models are the subglacial lakes also discovered in Antarctica (Kapitsa et al. 1996). Using airborne radio-echo survey of ice, more than 140 sub-ice lakes of unknown depth and composition were discovered in the 1970s. These environments completely isolated from the Earth's atmosphere could harbor important new biological discoveries. With an area of 10,000 km² and lying beneath several kilometers of ice, those particular niches are of tremendous interest for the astrobiologist. Data from the Galileo spacecraft reported the possible existence of a salty ocean underneath Europa's ice crust.

Lake Vostok is a particularly interesting case, first noticed in 1973 (Oswald and Robin G de 1973) by a scientist from the Scott Polar Research Institute using ice-penetrating radar. Due to the tremendous interest of the scientific community, the lake has been studied using several penetrating techniques such as airborne radio-echo sounding and penetrating radar imaging, as well as spaceborne radar altimetry. Finally, the lake was delimited in 1996 by British and Russian scientists. Lake Vostok (Siegert et al. 2001) is a 240 × 50-km lake, the largest of more than 140 subglacial lakes found under the surface of Antarctica and located at 4 km beneath the surface of the Central Antarctic ice sheet, with 22 cavities of liquid water. Lake Vostok is divided in two basins, separated by a ridge, and it is speculated to have different water composition in both of

them. Temperature of the water is around -3°C , but it remains liquid due to the high pressure from the weight of ice above it.

To probe the waters of Lake Vostok for life, without contamination, plans were initiated in 2001 by the NASA Jet Propulsion Laboratory to start with a melter probe – the so-called cryobot – which would melt down through the ice over Lake Vostok. The cryobot would carry with it a small submersible, called a “hydrobot,” which can be deployed when the cryobot has melted to the ice-water interface. The hydrobot would then swim off and “looks for signs of life” with a camera and other instruments.

But not only lakes but also an extensive network of waterways beneath the fast-moving Antarctic ice stream were discovered using NASA satellites. The water bodies beneath the ice crust constitute an important protected ecosystem to survey the habitability potential of the moon Europa and the survivability of life in such harsh conditions.

Svalbard in Norway has been the location for several astrobiological campaigns. Svalbard is an important Earth analogue where instruments similar to those that will fly on upcoming missions to Mars have been tested, as well as a field test site for rover prototypes. It is an archipelago in the Arctic, constituting the northernmost part of Norway and the northernmost populated place on the world. It is about midway between mainland Norway and the North Pole. This group of islands is located inside the Arctic Circle ranging from 74 to 81° north latitude and from 10 to 35° east longitude. Spitsbergen is the largest island. Its frozen soils with wide permafrost areas and glaciers allow life under extreme conditions and microbial habitability at very low temperatures to be studied.

This natural facility represents an important laboratory where a field campaign is organized every year by the astrobiological community and national space agencies. These campaigns, called Arctic Mars Analog Svalbard Expeditions (AMASE) (Younse et al. 2010), focus on learning how to search for life on Mars and how to develop and test the appropriate technology to do so, for example, the technology for future Mars missions,

on board of the Mars Science Laboratory (NASA) and the ► [ExoMars](#) (ESA) rovers. The conditions are so harsh that only ► [extremophiles](#) can thrive on the basaltic, carbonate-rich rocks, or in the glacial ice, scenarios that could be similar to equatorial Martian basalts or the icy regions of the Red Planet. If we want to search for life on Mars, we need to develop and test protocols to find past and present habitable environments and to prevent biological contamination that could arrive at Mars from our planet or could come back from Mars to the Earth in any Mars sample return mission. AMASE is developing systems to search for life and prevent contaminations. In fact, this research is not only focused on the planet Mars but also on any other icy planetary bodies that could potentially harbor microbial life, such as Europa, Titan, or ► [Enceladus](#). But not only cold environments are present on Svalbard. Also some hydrothermal sites are located in the Spitsbergen area. Life detection strategies based on antibody microarrays have been tested in those locations.

Rio Tinto, red river in English, takes its name from the dark-wine color of its waters. Rio Tinto is located in the southwest of the Iberian Peninsula, in the Huelva province (Andalusia, Spain), and originates in the Sierra Morena (Sierra de Aracena) mountains in the area called Peña de Hierro. Its waters flow south/southwest along 100 km to the Gulf of Cadiz (Atlantic Ocean). Rio Tinto is an extreme environment with a constant acidic pH (mean 2.3) and a high concentration of heavy metals (Fe, Cu, Zn, As, and Cr) in solution. Oxidized iron in acidic conditions (iron concentration in some locations is 22 g/l) is responsible for the red color of the waters. But their remarkable biodiversity dealing with these harsh conditions is present on the Rio Tinto water body (Bacteria, Archaea, photosynthetic and heterotrophic protists, yeast, and filamentous fungi). Geomicrobiological analysis of the Rio Tinto ecosystem reported that these conditions are the result of the metabolic activity of chemolithotrophic prokaryotes, mainly iron and sulfur oxidizers (Amils et al. [2002](#)). The system seems to be controlled by iron, which is not only used as an

electron donor but also as an electron acceptor, allowing a full iron cycle to operate. Furthermore, ferric ion is responsible for the maintenance of the constant pH of the ecosystem and can protect the different organisms thriving in its waters from damage due to UV radiation (Gómez et al. [2007](#)). Laminar, iron-rich stromatolitic formations are generated by the precipitation of different iron minerals on the surface of the biofilms that cover most of the rocks in the river. These structures are similar to ancient massive bioinduced laminated iron formations formed long before the first mining activities started in the area 5000 years ago (Fernández-Remolar et al. [2005](#)).

It is a terrestrial Mars analogue due to the chemistry and mineralogy of the system. Rio Tinto is located in an area rich in sulfides and iron minerals (Iberian Pyritic Belt), originating from an ancient hydrothermal system. Some locations on Mars are also rich in sulfur and iron oxide minerals. Basaltic volcanism is associated and widespread on Mars as well. On Earth, and Rio Tinto is a very good example of this, sulfide minerals form in hydrothermal systems associated with basaltic volcanism. Another important similarity between this extreme environment and Mars is the presence of some peculiar minerals. A notable case is ► [jarosite](#), an iron and potassium sulfate salt which is precipitated only at low pH solutions. This mineral appears precipitated on the microbial mats and the riverbed in the Rio Tinto system. Recently, the NASA Opportunity rover located jarosite on the Mars surface, a strong indication of the presence of acidic waters on Mars in the past.

Due to those analogies, the source area of Rio Tinto was chosen for the MARTE project implementation. Mars Analog Research and Technology Experiment (MARTE) was an ASTEP NASA co-funded program in collaboration with the Spanish government for Mars exploration technology development. The objectives of MARTE were (1) to search for and characterize subsurface life in Rio Tinto along with the physical and chemical properties and sustaining energy sources of its environment, (2) to perform an accurate simulation of a robotic Mars drilling mission to search for signs of life, and (3) to demonstrate the

maturity of the drilling, sample handling, and instrument technologies relevant to searching for life on Mars.

Also Martian habitability was tested under simulation experiments using acidophiles originally isolated from Rio Tinto in Mars planetary chamber simulation facilities (Gómez et al. 2010).

Atacama Desert is considered the driest place on Earth due to the rain shadow on the western side of the Chilean Coast Range, as well as a coastal inversion layer created by the cold off-shore Humboldt Current. Not only the low water activity level on its soil converts it on a Mars analogue but also the high levels of ultraviolet radiation and huge temperature swings, high winds, and dust storms capable of breaking down organic matter and salt precipitation that occurs due to the “camanchaca” (fog with salts dissolved which are deposited and precipitated during sunrise) coming from the Pacific Ocean in the morning. These physicochemical characteristics made the Atacama Desert a well-recognized Mars terrestrial analogue.

The Atacama Desert is located on a 1000-km strip of land plateau on the west side of Los Andes Mountains extending to the Pacific Ocean. This region is practically sterile because moisture is blocked by the Chilean Coast Range and the Andes Mountains. Several scientific missions have been focused on the Atacama Desert for life under extreme-condition studies as well as for the development and testing of life identification techniques for space missions by several national space agencies. The low microbial life detection level on the desert soil and low organic matter presence have made this environment an excellent natural laboratory for testing detection limits of the equipments (Cabrol et al. 2005). Also several robots and vehicles for Mars missions have been tested in the soil and harsh environmental conditions found in the Atacama Desert (Wettergreen et al. 1997).

Key Research Findings

The use of some extreme environments as terrestrial analogues provides the planetary science

research community and the space agencies with natural laboratories that have tremendous potential for studying the limits of life, the habitability of other planetary bodies, and for testing equipment and instrumentation to be used in the near-future upcoming missions. The resistance/adaptation/survivability of microorganisms at very low freezing temperatures on ice, under very high radiation doses, or high pressure in deep-sea ecosystems, as well as at very low pH in acidic environments, has led to a widening of the habitability potential on other planetary bodies such as Mars or icy Moons such as Europa, Titan, or Enceladus. Since extremophiles have been reported in the most extreme Antarctic conditions (Friedmann 1982) or at the driest place on Earth, Atacama Desert, which resembles the Mars surface or the ocean underneath Europa’s ice crust, our concept about life and its limits has widened considerably.

Applications

The applications from space missions and the knowledge of the limits of life would benefit from the research in the area of field analogues.

Terrestrial Planet

Tilman Spohn
International Space Science Institute, Bern,
Switzerland

Keywords

Planet

Synonyms

[Earth-like planet](#); [Rocky planet](#); [Telluric planet](#)

Definition

A terrestrial planet is a ► [planet](#) that resembles the ► [Earth](#) in size, surface geology, and chemical composition as indicated by its density. In our ► [Solar System](#), the terrestrial planets are ► [Mercury](#), ► [Venus](#), Earth, and ► [Mars](#), in order of distance to the Sun. In other Solar Systems – among exoplanets – a terrestrial planet would resemble the Earth in radius and average density. The term is sometimes used for Earth-like bodies that are not planets, such as the Moon and the Jovian satellite ► [Io](#).

Overview

The terrestrial planets orbit the Sun in the inner Solar System and consist mainly of silicate ► [rock](#) and iron, which make them distinguishable from the gas giants (► [Jupiter](#) and ► [Saturn](#)) and ice giants (► [Uranus](#) and ► [Neptune](#)) in the outer Solar System. The terrestrial planets of our Solar System are mostly solar or chondritic in

composition but depleted in ► [volatiles](#). They all have a similar chemically layered structure with an iron-rich core, a silicate ► [rock](#) ► [mantle](#) (mafic to ► [ultramafic](#) in composition), and a basaltic ► [crust](#). The core is likely to be liquid, but there may be a solid inner core such as in Earth. Although the mantle is solid, it can be viewed as an extremely viscous fluid on geological time scales except for a cold outer shell, the lithosphere. The lithosphere includes the crust and part of the mantle. On Earth, the lithosphere is broken into seven large plates that are continuously created at mid-oceanic ridges and recycled with the mantle at subduction zones through a process called ► [plate tectonics](#). Plate tectonics is driven by mantle convection in what is called the mobile lid regime. The other terrestrial planets of our Solar System have a contingent lithosphere that is pierced here and there by volcanic vents. For these planets, one speaks of single plate tectonics. The mantles underneath the plates in these planets are still convecting; however, it does so in what is called the ► [stagnant lid convection](#) mode. Through tectonic deformation and through volcanic activity, terrestrial planets convert heat and chemical energy into mechanical work. They may further convert heat and chemical energy into magnetic field energy by a ► [dynamo](#) in the core. Of the terrestrial planets, Earth and Mercury do have present-day magnetic fields. Remnant magnetization of Martian crustal rock suggests that Mars was self-sustained in its early history. It is not known whether or not Venus once had a magnetic field, but it has been speculated (Stevenson et al. [1983](#)) that it had one in its early history similar to Mars.

The terrestrial planets have atmospheres with masses that depend on the planet mass (through its gravity) and composition. The main component of Mars' and Venus' atmospheres is ► [carbon dioxide](#), while that of the Earth is molecular ► [nitrogen](#) and ► [oxygen](#), the latter a consequence of bioactivity. The atmospheric pressure on the surface of the Earth is 1 bar (100 kilopascals), and on Venus, it is 93 bar. The average surface temperature is 288 K on Earth and 735 K on Venus. On Mars, the average surface pressure is 0.006 bar, and the average surface temperature is 210 K. The

average surface temperature on Mercury is 440 K, with the temperature varying between 105 K at night and 700 K during daytime.

The terrestrial planets have about 0.0005% of the mass of the Solar System, while the Sun holds 98.8% of the total mass. Mercury is the smallest among this group of planets with almost no atmosphere ($<10^{-12}$ bar), and it has the second highest bulk density (5427 kg m^{-3}). The surface of Mercury is subject to high temperature variations and is extremely cratered. Venus is the sister planet of Earth concerning size, and even the density is similar (5204 kg m^{-3}). Its peculiarity is the very thick atmosphere. It is shielded by a layer of clouds, impenetrable for the visible part of the ► [electromagnetic spectrum](#). This is why Venus' surface is explored using radar and infrared imaging. Earth is the biggest among the rocky planets with the highest density (5515 kg m^{-3}). Furthermore, it is the only planet on which we know to date that life developed. The ► [Moon](#) is about one fourth of the size of Earth and has about two thirds of the bulk density of Earth. The Moon and Earth are locked in a 1:1 spin orbit coupling; thus, the Moon shows almost the same face toward the Earth at all times. Mars is about half the size of Earth, has a very thin atmosphere, and is the least dense terrestrial planet (3933 kg m^{-3}). Nevertheless, it is believed that Mars had, after the Earth, the best chance to develop some primitive form of life in the past.

[Transiting exoplanet survey satellite](#)

Definition

TESS, or Transiting Exoplanet Survey Satellite, is a NASA satellite which has been observing near and bright stars since 2018. Its goal is to find

transiting planets around these bright stars. These planets are particularly well suited for follow-up studies such as not only radial velocities to derive their mass but also spectroscopy of the planets' atmosphere.

History

TESS was proposed in 2008 as a NASA mission to survey the entire sky for transiting planets in order to find the nearest and brightest systems. TESS was selected by NASA for a Phase A study for a so-called Small Explorer mission in May 2008 but subsequently was not selected for a flight opportunity. TESS was resubmitted as a candidate for what NASA calls an Explorer mission in 2010 and was finally approved in 2013. The satellite was successfully launched in April 2018 on a SpaceX Falcon 9 rocket. Since then, it has been surveying 200,000 stars over the whole sky for transiting planets.

Overview

Today, the field of exoplanets has moved beyond the “simple” detection of planets to their characterization, in particular the characterization of their density, which leads to knowledge of their internal structure and the characterization of their atmosphere. To know the density of planets, one needs to know their radii (through the transit method) and their masses (through radial velocity of transit timing measurements). Most of the Kepler satellite planets were detected around faint stars (by construction of the satellite), and these systems were consequently extremely challenging for radial velocity follow-up.

To circumvent this limitation, and using a strategy comparable to the CHEOPS mission, TESS only targets bright stars. These stars are 30–100 times brighter than the stars observed by the Kepler satellite and K2. Bright stars are then much easier to follow-up with spectrographs on the ground, such as HARPS, HARPS-N, or ESPRESSO. These radial velocity follow-ups

allow to derive the mass of the planets and therefore to constrain their densities.

TESS uses an array of small telescopes and has the sensitivity to detect planets as small as the Earth, even a few in the habitable zones of cool stars. It surveys almost the whole sky, which represents an area 400 times larger than the area monitored by Kepler. The sky area TESS surveys is divided in 26 different sectors. It stares at each sector for at least 27 days before moving to the next. The southern ecliptic hemisphere was observed during Year 1 and 3 of the mission, and the northern ecliptic hemisphere was observed during Year 2 and a part of Year 4. In November 2021, when this entry was submitted, the telescope was pointing toward the ecliptic, observing some of the K2 campaign fields (see <https://tess.mit.edu/observations/>).

Since the beginning of its operation (40 sectors observed), TESS has detected potential transiting signals around 4471 TOIs (TESS Object of Interest), with almost 800 planetary candidates with radii smaller than 4 Earth radii. Of these 4471 signals, 154 were confirmed as TESS planets using follow-up observations (with ground-based photometry, for instance, with the network LCO-GT, or MEarth, TRAPPIST, and SPECULOOS...).

Among them, TOI-700 d (Gilbert et al. 2020) is the first Earth-size exoplanet discovered by TESS in its star's habitable zone, the range of distances where conditions may allow the presence of liquid water on the surface. This habitable-zone planet with a period of around 37 days is one of three orbiting TOI-700, a cool M dwarf with around 40 percent of the Sun's mass and located about 100 light-years from Earth. The climate of the habitable zone planet TOI-700 d has been investigated with 3D climate models to show that it can maintain surface liquid water under a variety of atmospheric compositions (Suissa et al. 2020). Although the atmosphere of this planet will not be characterizable with the JWST, it motivates the community to think about a next generation of instruments which could.

Tethys

Therese Encrenaz
LESIA, Observatoire de Paris – Section de
Meudon, Meudon, France

Definition

Tethys is one of the midsized icy satellites of ► [Saturn](#). Discovered by Giovanni Domenico ► [Cassini](#) in 1684, it orbits at a distance of 294,700 km (or 4.9 Saturnian radii) from Saturn. Its diameter is 1060 km. Images taken by the Voyager 2 spacecraft in 1981 show a variety of terrains,

with some ancient, heavily cratered regions including the large Odysseus basin that is over 400 km in diameter and a more recent, remodeled surface with a large canyon, Ithaca Chasma, which is about 1000 km long and 100 km wide. The density of Tethys is 1.0 g/cm^3 , which indicates a rather pure water-ice satellite. Two other small satellites, Calypso and Telesto, are located on the same orbit as Tethys.

On Earth, the so-called Tethys ocean separated the continents of ► [Gondwana](#) and ► [Laurasia](#) during the Mesozoic.

Tharsis

Ernst Hauber
Deutsches Zentrum für Luft- und Raumfahrt
(DLR) e.V., Institut für Planetenforschung,
Berlin, Germany

Definition

Tharsis is a region on ► [Mars](#) which is the largest known volcanic province in the ► [Solar System](#), with an area of $3 \times 10^6 \text{ km}^2$ and a volume of

$3 \times 10^8 \text{ km}^3$. It is characterized by a huge topographic bulge (up to 10 km above the Martian datum), which is topped by about a dozen very large and hundreds of small volcanoes. Most of the surface consists of basaltic lava flow fields. The current topography of Tharsis is mainly the result of volcanic loading, and only a small part may be due to dynamic uplift, perhaps supported by a mantle (super) plume. Tharsis is very old, and its formation may have reoriented the planet's spin axis, so that the center of Tharsis is now located near the equator. Tharsis-centered tectonics dominate the entire western hemisphere of Mars.

Theia

Synonyms

[Orpheus](#)

Definition

Theia is the name given to a hypothetical proto-planet or planetesimal, roughly the size of Mars, which is thought to have collided with the proto-Earth, ejecting material into orbit to form the Moon. The hypothesis of Moon formation by Theia is called the “Moon-forming Giant Impact hypothesis.”

Overview

The impactor's name comes after the mythical Greek goddess *Theia* who gave birth to the Moon goddess, *Selene*. The most widely accepted model for the Moon origin is that Theia struck the proto-Earth at an oblique angle, adding 10% of the Earth's mass and generating a hot, partly vaporized debris disc from which the Moon accreted (Canup and Asphaug 2001). The timing of the impact and the nature of the impactor have been the focus of numerous studies and speculations, not completely solved.

The timing of the impact could be solved either precisely determining the age of the Moon (Halliday 2008) or the age of the Earth's core differentiation, if the impact completely melted the Earth mantle and favored the mantle-core differentiation (Jacobson et al. 2014). It has also been suggested that the early Earth catastrophic degassing of the mantle and subsequent atmosphere formation was triggered by the Moon-forming impact. Thus, dating this earlier episode of Earth evolution might resolve the issue (e.g., Avicé and Marty 2014).

Radiometric dating of lunar samples gave ages of the lunar crust spanning from 4.29 to 4.47 Ga with earlier crust Rb-Sr ages of 4.48 ± 0.02 Ga or 70–110 Ma after the beginning of the Solar system (Halliday 2008). Extinct radiochronometers were also used to determine the timing of the Moon formation, because the high temperature reached during the Moon-forming impact (5000–10,000 K) should have reset any radiometric clock in the colliding bodies. Because Hf is a lithophile element, W is moderately siderophile element, and ^{182}Hf has a short half-

life of 8.9 Ma over which it decays to ^{182}W , the ^{182}Hf – ^{182}W system can be used to constrain the timescale of metal–silicate (i.e., core–mantle) differentiation of planetary objects within ~ 7 half-lives, that is, the first 60 Ma since the Solar system formation. Obtained ^{182}Hf – ^{182}W ages were affected by cosmogenic production of ^{182}W and from erroneous assumption of the initial chondritic $^{182}\text{Hf}/^{180}\text{Hf}$ ratio. However, corrected ^{182}Hf – ^{182}W ages were still younger than the older lunar crust estimate, ca. 45 Ma after the formation of the Solar system. The same ^{182}Hf – ^{182}W chronometer applied to the differentiation of the mantle–core system gave older ages of 93 ± 32 Ma 95 ± 32 Myr after the Solar system condensation (Jacobson et al. 2014). Finally, Avice and Marty (2014) based on the extinct radionuclides ^{129}I – ^{129}Xe (half-life of 15.6 Ma) and ^{244}Pu – 131 – ^{136}Xe (half-life of 80 Ma) concluded that the Xe formation interval for the Earth atmosphere system is ca. 40 Ma after the beginning of Solar system formation, to be assumed as lower limit of the Moon-forming impact.

The composition of Theia and thus its source region within the Solar system is also debated. Support for the Giant Impact hypothesis comes from the similarity between the oxygen isotopic composition of the Earth and the lunar rocks. The oxygen isotopic composition of the Moon is also close to that of the enstatite chondrites, which would indicate that the impactor Theia came from the same inner region of the Solar system where the Earth formed. However, an isotopic similarity between the Earth and the Moon is difficult to reconcile with the fact that the Moon would be made of 90% of Theia and 10% of the proto-Earth. Measurements of isotope ratios of terrestrial, Martian, and meteorite samples show that the bodies in the early Solar system were isotopically heterogeneous. It is therefore expected that Theia and proto-Earth were isotopically distinct. Although several processes could reconcile this view, such as an isotopic re-equilibration in the aftermath of the impact, recent analyses of lunar samples revealed 12 ± 3 parts per million difference in the oxygen isotopic

composition with the Earth (Herwartz et al. 2014). They also showed that the Bulk Silicate Earth has an oxygen isotopic composition different from enstatite chondrites, thus not excluding that these meteorites formed the majority of Theia. An alternative hypothesis to explain these small, but resolvable isotopic differences is that carbonaceous chondrites might be the Theia precursors, implying a source region located in the outer part of the Solar system where water and volatile-rich meteorites would have formed (Herwartz et al. 2014). Resolving the source region and the nature of the Theia impactor has implication far beyond the Moon origin but could also be important for determining the carrier of oceanic water on the telluric planets.

Thermal Radio Jets

Guillem Anglada
 Instituto de Astrofísica de Andalucía, CSIC,
 Granada, Spain

Keywords

Star-formation · Jets · Protostars ·
 Protoplanetary disks · Free-free emission ·
 Radio Astronomy

Definition

Thermal radio jets are sources of free-free emission at radio wavelengths that trace collimated, partially ionized material ejected at high velocities (100–1000 km/s) from a region very close (<10 au) to the protostar. Radio jets are usually weak (<1 mJy) radio sources with positive spectral indices (i.e., with flux density increasing with frequency). When observed with high enough angular resolution they look elongated. Thermal radio jets are preferentially associated with protostars that are deeply embedded in molecular clouds, and trace the base of the larger scale jets (several 1000 au to several pc) observed at optical and infrared wavelengths, and that are associated with bipolar flows.

Overview

Thermal radio jets are partially ionized and are therefore relatively weak sources (a few mJy at most) of free-free radio continuum emission. The slope of the flux as a function of frequency in the logarithmic space is called the “spectral index” and, depending on the optical depth, the free-free spectral index of an ionized region ranges from -0.1 (optically thin) to 2 (optically thick). As shown by Reynolds (1986), a conical thermal radio jet moving at a constant velocity will have a characteristic spectral index of 0.6 , in agreement with the median of observed values which is about 0.5 (Anglada et al. 2018).

Both HII regions and thermal radio jets are free-free radio sources. However, in addition to the characteristic spectral index of thermal radio jets, there are other differences between these two kinds of radio sources. Radio jets are elongated, whereas HII regions do not usually show an elongated morphology. In addition, thermal radio jets present outflow velocities of 100–1000 km/s, while HII regions expand at much lower velocities, of a few km/s. Finally, an important difference concerns the ionization mechanism. While HII regions are ionized by stellar UV photons the proposed ionization mechanism of thermal radio

jets are the shocks associated with the outflowing material (Curiel et al. 1989).

As a consequence of the different ionization mechanism, HII regions are only found to be associated with high luminosity massive stars, which have a high rate of ionizing UV photons, while thermal radio jets are found to be associated with young stars across the whole mass spectrum, from massive protostars to very low mass objects, possibly even to proto-brown dwarfs (Anglada et al. 2018). The radio flux of thermal jets normalized by the distance squared (i.e., the radio luminosity) has been found to be linearly correlated (in log-log space) with both the momentum rate (force) of the outflow and with the bolometric (i.e., integrated over the whole electromagnetic spectrum) luminosity of the protostar (Anglada et al. 1992, 1998, 2018). These correlations are interpreted to be a consequence, respectively, of the ionization mechanism (related to outflow shocks), and of the connection between outflow and accretion (from which most of the protostellar luminosity originates). They can be used to infer the luminosity of protostars, to distinguish between HII regions and thermal radio jets, and to investigate the evolutionary stage of young massive stars.

There are also similarities and differences between the radio sources corresponding to thermal radio jets from protostars and those corresponding to radio jets from black holes. Radio jets from protostars trace material moving at nonrelativistic velocities and are thermal free-free emitters. In contrast, radio jets from black holes trace material moving at relativistic velocities and emit nonthermal synchrotron radiation at radio wavelengths. Nevertheless, in some radio jets from protostars, in addition to the thermal core near the origin, there is evidence for the presence of nonthermal emission, usually in distant knots at distances 10,000–100,000 au from the origin. This nonthermal radio emission is attributed to synchrotron radiation from a small population of electrons that have been accelerated up to relativistic velocities in strong shocks of the jet against dense material in the

surrounding molecular cloud where the protostar is forming (Carrasco-González et al. 2010; Rodríguez-Kamenetzky et al. 2017; Anglada et al. 2018).

Thermochemical Equilibrium

► Thermodynamical Chemical Equilibrium

Thermodynamical Chemical Equilibrium

Bruno Bézard

LESIA, Observatoire de Paris, Meudon, France

Keywords

Chemical equilibrium · Kinetics · Planetary atmospheres · Thermochemistry

Synonyms

Law of mass action; Thermochemical equilibrium

Definition

Thermodynamical chemical equilibrium is the state of a closed system in which the concentrations of the various species have no tendency to change with time. This is a dynamical state in which chemical reactions proceed at equal rates in the forward and reverse directions. Under conditions of constant temperature and pressure, the equilibrium composition corresponds to a minimum in the Gibbs free energy of the system.

Overview

The laws of thermodynamical chemical equilibrium allow us to calculate the equilibrium composition of any chemical system with a given elemental composition as a function of pressure and temperature. However, a chemical system can reach its equilibrium state only if the reactions proceed more rapidly than other processes at

work in the system, such as dynamical mixing. As reaction rates depend sensitively on temperature and species' concentrations, chemical equilibrium overall applies to warm and relatively dense astrophysical objects, such as stars or the deep atmospheres of ► [giant planets](#). On the other hand, cold and less dense objects, for example, the interstellar medium or upper planetary atmospheres, are far from chemical equilibrium due to a variety of disequilibrium processes. Thermochemical calculations applied to giant planets (solar system and extrasolar) and brown dwarfs (BDs) are discussed.

Basic Methodology

The Equilibrium Constant

The equilibrium constant (K) relates the relative concentrations of the compounds (reactants and products) involved in a chemical reaction system at equilibrium. It is defined as the product of the activities of the products divided by the product of the activities of the reactants at equilibrium. For a reaction expressed symbolically as:

where R_i denotes reactant i , P_j product j , and the ν_i and the ν_j the corresponding stoichiometric numbers, K is expressed as:

$$K = \frac{\prod_j a_j^{\nu_j}}{\prod_i a_i^{\nu_i}} \quad (2)$$

where a_i and a_j are the activities of the reactants and products, respectively. The ► [activity](#) is a thermodynamic property that measures the “active” concentration of a species in a mixture. In nonideal gases or solutions, it differs from other measures of concentration (such as partial pressures and mole fractions) due to electrostatic interactions between the various species.

For gaseous compounds, the activities are often replaced by the partial pressures p_i and p_j expressed in bars, assuming an ideal-gas mixture. For example, the equilibrium constant of the gas-phase reaction

is given by $K = \frac{P_{\text{CO}}P_{\text{H}_2}^3}{P_{\text{CH}_4}P_{\text{H}_2\text{O}}}$. When pure substances, liquids or solids, are involved in the reaction, they do not appear in the equilibrium constant (their activity is 1). In the case of aqueous dilute solutions, the activities can be replaced by the molar concentrations of the solutes, expressed in mol l^{-1} .

At a given temperature T , K is a constant, independent of pressure. For historical reasons, this is known as the law of mass action. The equilibrium constant is related to the standard Gibbs ▶ **free energy of the reaction** ΔG^0 (standard molar Gibbs free energy of formation of the products minus that of the reactants) at temperature T by:

$$K = \exp\left(-\frac{\Delta G^0}{RT}\right) \quad (3)$$

which enables us to calculate the equilibrium constant of any reaction, and thus the equilibrium composition of the system, from tables of thermodynamical data (e.g., Chase et al. 1998). The variation of K with temperature is given by the Van't Hoff equation:

$$\frac{d \ln K}{dT} = \frac{\Delta H^0}{RT^2} \quad (4)$$

where ΔH^0 is the standard ▶ **enthalpy** of the reaction at temperature T (standard molar enthalpy of formation of the products minus that of the reactants) and R is the universal gas constant.

The response of the equilibrium composition to changes in conditions (temperature, pressure, concentration of a species) is summarized by Le Chatelier's principle, which states that a system at equilibrium responds in a way that tends to minimize the effect of the disturbance. For example, the system responds to a compression by

reducing the number of molecules in the gas phase, shifting the reactions to the side with fewer moles of gases. Increasing the temperature favors the products of ▶ **endothermic** ($\Delta H^0 > 0$) reactions and the reactants of ▶ **exothermic** ($\Delta H^0 < 0$) reactions, as evidenced by Eq. 4.

Kinetic Considerations

Thermodynamics do not tell us how fast the equilibrium state of a chemical system has reached or even if it can be attained in less than the age of the solar system. This depends on the reaction mechanisms. A reaction may be highly favored thermodynamically but inhibited kinetically. For a homogeneous ▶ **bimolecular reaction** ($A + B \rightarrow \text{products}$), the reaction rate is given by:

$$-\frac{d[A]}{dt} = k[A][B]. \quad (5)$$

where k is the so-called rate constant and $[A]$ and $[B]$ the reactants' concentrations. In most cases, k can be expressed by the Arrhenius equation:

$$k = Ae^{-\frac{E_a}{RT}} \quad (6)$$

where A is the pre-exponential factor and E_a is the ▶ **activation energy**, which varies typically from tens to hundreds of kJ per mole for gas-phase reactions. High activation energy implies that the rate constant depends strongly on temperature.

Equations 5 and 6 indicate that reactions proceed more rapidly as temperature and concentrations increase (reactions may also be accelerated by the presence of catalysts). For this reason, chemical equilibrium is overall achieved in warm and relatively dense astrophysical objects or regions, that is, stars, brown dwarfs, central regions of circumstellar disks, ▶ **hot Jupiters** and hot Neptunes, the deep atmosphere of giant planets, and to some extent the deep atmosphere of ▶ **Venus**. On the other hand, cold and less dense media are far from chemical equilibrium. These media include the interstellar medium; the outer regions of protoplanetary disks; the comets; the atmospheres of Titan, Mars, and Earth; and the upper atmospheres of all planets.

Disequilibrium Processes

The latter objects can maintain a nonequilibrium chemical composition by exchanging energy of different entropy (or mass) across their boundaries. Important nonequilibrium processes are the following:

- Cosmic ray irradiation. This is the dominant source of ionization in cold interstellar cloud cores, which initiates rich ion-molecule chemistry.
- Photochemistry and electron-induced chemistry. These processes (using photons from the central star and electrons from the planet's magnetosphere) create a wealth of non-equilibrium compounds in the upper planetary atmospheres: hydrocarbons on the giant planets and Titan, nitriles on Titan, oxygen compounds on Mars and Venus (CO, O₂, O₃, and H₂O₂), possibly CO₂, and other species in hot Jupiters.
- Shock chemistry. Shock heating during accretion onto protoplanetary disks leads to some chemical reprocessing of the disk material. Also, cometary impacts in planetary atmospheres produce compounds exogenous to the ambient air (e.g., CO, HCN in ► [Jupiter](#) following the impact of Comet Shoemaker-Levy 9).
- Electrical discharges. Lightning and other electrical phenomena are a source of non-equilibrium species in planetary atmospheres, such as NO on Earth and Venus, and possibly oxidants on Mars.
- Biotic activity. Life substantially affects the chemical composition of the Earth's environment, as reflected, for example, by the high concentration of reactive oxygen in the atmosphere.
- Transport of matter in a thermoclinic environment. Turbulent mixing can transport species from hot regions where they are thermodynamically stable to colder regions where their chemical conversion is kinetically inhibited. It can affect the composition of the outer atmospheres of the giant planets and brown dwarfs. In the solar nebula and protoplanetary disks, chemical "quenching" by outward motion (and

also by overall radiative cooling) is thought to be highly important.

Key Research Findings

The equilibrium composition of material characterized by a given elemental composition can be calculated, as a function of temperature T and pressure p , from the laws of chemical equilibrium. Gas mole fractions ($x_i = p_i/p$) and the presence of condensates can be derived by writing the mass balance equations, one per element, the equilibrium constants K_i for forming the different gases, and those between gases and condensates.

Thermochemical equilibrium calculations have been used to predict and interpret the composition of giant planets (Fegley and Lodders 1994), extrasolar giant planets (EGPs) (Lodders 2010; Madhusudhan et al. 2016), and brown dwarfs (Lodders and Fegley 2006, Fig. 1). Models of thermochemical equilibria in Venus' deep atmosphere and surface-atmosphere interactions, not discussed here, are presented in Krasnopolsky (2007) and Fegley et al. (1997).

Giant Planets

Assuming solar composition material, the models reproduce the main features of the composition of Jupiter's and Saturn's observable troposphere, namely:

- C and N are predominantly in the form of CH₄ and NH₃, respectively.
- NH₃ and H₂O are depleted in the upper troposphere ($T < 150$ K and $T < 280$ K, respectively) due to condensation.
- H₂S is present in Jupiter below the 2-bar level, a consequence of the condensation of iron at deep levels (preventing the removal of S by FeS formation), but depleted in the upper troposphere due to the formation of ammonium hydrosulfide (NH₄SH) at 210 K.
- Silane (SiH₄) is absent due to the formation of silicates in the deep atmosphere. More generally, refractory elements are sequestered into deep high-temperature clouds.

Thermodynamical Chemical Equilibrium, Fig. 1 Major features of the equilibrium chemistry of solar composition material as a function of temperature and pressure. *Solid lines* delineate the regions above which the labeled condensate is present and the corresponding minor element removed from the gas phase. The *dots* on the Al-Ca-oxides curve correspond to different Al-bearing condensates and those on the Ti-Ca-

oxides curve to different Ti-bearing condensates. The *white dots* on the enstatite (*en*) and iron (*Fe*) curves indicate melting points. The *dotted curves* indicate equal abundances of CO and CH₄ and of N₂ and NH₃. Also shown are temperature profiles of an M dwarf (*dM*) with $T_{\text{eff}} = 2200$ K, the brown dwarf Gl 229B ($T_{\text{eff}} = 960$ K), and Jupiter. (From Lodders and Fegley (2006))

On the other hand, a few species (CO, PH₃, AsH₃, and GeH₄) have been detected with abundances well above their equilibrium values. Their presence can be explained by transport from the hot deep atmosphere, where they are stable, to colder observable levels where the timescale for chemical conversion is larger than the mixing time (Fig. 2). These nonequilibrium species can be used as probes of the convective mixing and of deep elemental abundances (e.g., O/H in the case of CO, Visscher et al. 2010).

Hot Jupiters and Brown Dwarfs

Thermochemical models of extrasolar giant planets (EGPs), assuming radiative-convective

equilibrium and a Jupiter-like composition, predict that EGPs with effective temperature (T_{eff}) below 150 K have, like Jupiter and Saturn, high NH₃ clouds and those in the range 150–250 K high H₂O clouds. EGPs with T_{eff} in the range of 250–1000 K are relatively cloudless above the 10-bar level, whereas hot Jupiters with T_{eff} in excess of ~ 1200 K exhibit high iron and silicate clouds in their atmospheres, which has important consequences on their emission spectra. In cool EGPs ($T_{\text{eff}} < \sim 500$ K), the dominant carbon- and nitrogen-bearing compounds are CH₄ and NH₃, whereas in hot Jupiters ($T_{\text{eff}} > \sim 1200$ K), CO and N₂ dominate at all levels. Na and K are in gaseous form above,

Thermodynamical Chemical Equilibrium, Fig. 2 Vertical profiles of oxygenated compounds in Jupiter's deep atmosphere derived from thermochemical equilibrium and kinetic-diffusion model calculations. A solar O/H elemental ratio is assumed. *Dotted grey lines* indicate

thermochemical equilibrium. *Solid lines* show the profiles when reaction kinetics and vertical eddy mixing is included. (From Visscher et al. 2010; reprinted from Icarus, with permission from Elsevier)

respectively, ~ 1000 and ~ 800 K, so that these gases, that are strong absorbers of visible light, play a major role in the heat balance of hot Jupiters. Their upper atmospheres may also contain TiO and VO, molecules with strong optical bands, leading to very intense stellar heating. Tidally locked hot Jupiters are predicted to exhibit a large day-to-night thermal contrast, leading to horizontal variations in the equilibrium chemistry, such as the conversion of CO to CH₄ or the condensation of sodium at night. The detection of large amounts of CO in relatively cool irradiated EGPs ($T_{\text{eff}} < \sim 1000$ K) suggests that chemical quenching of the CO–CH₄ system occurs as on Jupiter.

The equilibrium chemistry of brown dwarfs (BDs), from the coolest T dwarfs at $T_{\text{eff}} \sim 700$ K to the hottest M dwarfs at 2000–2500 K, resembles the molecular gas and condensate chemistry of hot Jupiters as concerns, for example, the condensation of silicate and Fe clouds, the presence of alkali metals and that of TiO and VO at high temperature (Fig. 1). On the other hand, isolated BDs have steeper temperature profiles than

irradiated EGPs, which leads to differences in the equilibrium chemistry, such as carbon being in the form of methane in the outer atmosphere of BD Gliese 229B and in the form of CO in an EGP with the same T_{eff} (960 K). The detection of CO in Gliese 229B also points to nonequilibrium chemistry.

Thermonatrite

Daniele L. Pinti

Geotop, Research centre for the dynamics of the Earth system, Université du Québec à Montréal, Montréal, QC, Canada

Chemical Formula

Definition

Thermonatrite is a non-marine evaporite mineral of the orthorhombic crystal system. It is often found in association with halite (NaCl), trona ($\text{Na}_3(\text{CO}_3)(\text{HCO}_3) \cdot 2\text{H}_2\text{O}$), and natron ($\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$) in alkaline lakes formed in arid climates (► [soda lakes](#)). It can also form as an exhalative product of fumaroles or from alteration of natrite (Na_2CO_3). Detection of thermonatrite on Mars or other planetary surfaces could be an indication that alkaline or hypersaline lakes had formed in the past under reducing and dry environments.

UAM-CSIC, Madrid, Spain

Keywords

High temperature · Hot springs · Thermal environment

Synonyms

Caldophile

Definition

Thermophiles (literally heat lovers) are organisms that grow at temperatures above those (25–40 °C) that sustain most life forms. Typically, a thermophile shows maximum growth rates at temperatures above 45 °C. Most are prokaryotes although a few thermophilic eukaryotes also exist. Depending on the temperature range for growth, thermophiles are divided into different categories like moderate or facultative thermophiles, which are able to grow below 40 °C, extreme or obligate thermophiles, which grow at temperatures from 55 °C to 80 °C, and ► [hyperthermophiles](#), with optimum growth temperatures above 80 °C.

History

The first thermophiles were described at the end of the nineteenth century in isolates from the Seine River and in studies on cyanobacteria in hot springs. In the early twentieth century, moderate thermophiles were identified as contaminants in the sugar industry and in compost. In the second half of the twentieth century, thermophilic enzymes started to be used in industry, especially for detergents. Following the description of the DNA structure, it was proposed that the upper

limit for life was around 73 °C, the melting temperature of DNA. However, Thomas D. Brook and coworkers isolated and described organisms thriving at well over this limit in hot springs of Yellowstone National Park. The subsequent work by Wolfrang Zillig and Karl Stetter among others and improvements in submersibles and isolation methods allowed the identification of (hyper)thermophiles able to grow above 110 °C.

Overview

In contrast to the heat resistance (thermotolerance) shown by plant seeds or bacterial spores, (based on specific properties such as cytoplasmic dehydration and viscosity increase limiting the thermal movements of molecules), the macromolecular components of thermophiles have adapted to function optimally at high temperatures. Strategies of thermal adaptation include modified composition of their cytoplasmic membranes to keep appropriate fluidity under the temperature range of optimum growth and increased compactness of their proteins through appropriate changes in their amino acid sequence or specific modifications of bases in small RNA segments. Most thermophiles have an elevated G + C content in their DNA compared to organisms that grow at lower temperatures, leading to the hypothesis that this is a specific trait of thermophiles. However, the existence of hyperthermophiles with a low G + C content invalidates this conclusion. Further adaptations to higher temperatures require the presence of increased concentrations of ► [compatible solutes](#) like ectoine or polyol-phosphate derivatives, or the presence of reverse gyrase, to decrease the melting effects of temperature on DNA. Thermostable enzymes, the enzymes of thermophiles, have applications of great relevance such as the development of the polymerase chain reaction (PCR) and derived techniques that use DNA polymerases from thermophilic organisms (e.g., ► [Taq polymerase](#)). In addition, thermostable enzymes are usually more resistant than conventional enzymes to organics and detergents, making them excellent candidates for industrial applications where severe conditions are encountered. From a biological point of view, the relationship between

thermophilic character and an ancient phylogenetic origin is commonly discussed, leading to the idea that these organisms are a window to the time when life first originated on earth.

Thermosphere

Amanda Brecht

NASA Ames Research Center, Moffett Field,
CA, USA

Definition

The region of an atmosphere called the thermosphere is characterized by an increase in neutral

temperature as a function of altitude and asymptotes to a relatively constant temperature. The corresponding neutral atmospheric density is decreasing with altitude. The top of the region is bounded by the thermopause (or exopause/exobase), defined to be the region where the mean free path of particles is longer than a scale height. The bottom boundary is the mesopause, which is defined by the change in the thermal gradient from negative to positive (i.e., temperature begins to increase above the mesopause).

Energy is transported between the lower atmosphere (i.e., troposphere, mesosphere) and space (exosphere) through the thermosphere. The processes involved in the energy transport heavily influence the behavior and structure of the thermosphere. The relative importance of these processes depends greatly on the planetary environment and is related to how energy is absorbed, dissipated, and transported in the thermosphere. As can be imagined energy transport is a complex process. In the paragraphs below a brief description of the major processes is provided.

For planets closer to the Sun, the main source of energy (heat) entering the thermosphere comes from EUV/UV radiation, which varies depending on the solar activity. The Sun has a dominant ~11 Earth year cycle variation, which alone provides large variations. However, the Sun can have shorter and more sporadic variations; such as solar flares and coronal mass ejections. Therefore, the thermosphere temperature and structure will also vary depending on the solar activity by expanding during active times (more energy absorbed by the atmosphere) and compressing during quiet times (less energy absorbed by the atmosphere). Furthermore, EUV/UV radiation and other high energy particles from the Sun generates an ionosphere. An ionosphere is a region of atmosphere with a high concentration of ionized particles that usually coexists with the thermospheric neutral atmosphere, and they are coupled through nonlinear connections (e.g., chemical reactions, ion-neutral drag).

The thermosphere also absorbs energy from auroral processes (e.g., Joule heating) and

particle precipitation from the magnetosphere. The magnitude of these two processes is connected to the size of the planet's intrinsic magnetic field. For example, auroral processes at Earth are a dominant heat source during magnetic sub-storms while EUV/UV dominates during non-storm times, and for Jupiter auroral processes are just as important as EUV/UV heating. Conversely, Venus and Mars thermospheres are driven by EUV/UV radiation and particle precipitation.

The main processes of heat loss in the thermosphere are thermal IR (Infrared) radiation and thermal conduction. The magnitude of cooling by thermal IR radiation in the thermosphere is related to the atmospheric constituents and density. Due to the general decrease of density within the thermosphere (low collision rates), specific chemical species radiating in the IR will depart from the Local Thermodynamic Equilibrium (LTE) assumption and depend on the Non-LTE assumption. Non-LTE occurs when energy is exchanged more rapidly with the radiation field (or other energy sources) rather than through collisions with other molecules. The cooling of the thermosphere, via IR radiation, is most effective in the mid-lower thermosphere. Thermal conduction effectively cools an atmospheric region by transporting heat from areas of large vertical temperature gradients down to lower altitudes, so the larger the gradient the more efficient thermal conduction cools.

Varying processes produce irregular energy absorption and dissipation, which in turn produces pressure gradients that drive neutral winds. Furthermore, the pressure gradients contribute to energy transport and impact the thermospheric structure and composition. The dayside of a planet will warm and expand the atmosphere with corresponding upwelling motions. This atmospheric expansion generates adiabatic cooling. While the nightside tends to be cooler due to a lack of a major energy source (the Sun), the atmosphere compresses with downwelling motions. This will produce adiabatic heating. The adiabatic cooling and heating processes will compete with other

energy processes to regulate the thermal structure but are most effective with large, varying global scale neutral winds (relative to the planet).

The thermosphere is connected to the lower atmosphere predominantly through wave mechanisms; tides (migrating and non-migrating), large-scale planetary waves, and small-scale gravity waves. Waves propagate upwards and deposit momentum and energy when they become unstable ("break"). The wave deposition perturbs pressure, neutral wind, temperature, and density fields. The sources of waves range from auroral process to topography, and convection in the middle/lower atmosphere.

Lastly, the method by which the energy is directed within a thermosphere is also dependent on the density and chemical species (such as the thermal IR radiation). It is important to note that the distribution of the thermospheric composition can be split into homosphere (gases homogeneously well mixed) and heterosphere (gases diffusively separate). The homosphere is dominated by heavier chemical constituents and is driven by eddy or turbulent diffusion. The heterosphere is dominated by lighter chemical constituents and is typically driven by molecular diffusion, where compounds are separated by molecular weight. The boundary between a diffusive separated region and a well-mixed region, the homopause, varies based on temperature so the boundary can vary in altitude.

Definition

In chemistry, thiocyanate is the small molecule SCN^- (the conjugate base of thiocyanic acid HSCN). Organic compounds containing the functional group SCN are also called thiocyanates. Thiocyanate may be an important prebiotic compound as it forms robustly from cyanide and elemental sulfur:

It is relatively stable to hydrolysis but is oxidized by H_2O_2 . SCN^- has also been found to be an effective yet unpredictable condensing agent for peptide bond formation. SCN^- may be a significant [precursor](#) to thioesters in prebiotic chemistry and has been shown, when oxidized with H_2O_2 , to form condensed phosphates in high yield. SCN^- shares its negative charge approximately equally between sulfur and nitrogen; thus SCN^- can act as a nucleophile at either sulfur or nitrogen. It may react with amines and other nucleophiles at the central carbon atom. Reaction with amino acids may yield thiocarbamates, thiohydantoin, and ultimately hydantoin.

 of Technology, Atlanta, GA, USA

Definition

Thioesters are esters in which the linking oxygen atom is replaced by sulfur. They are the product of dehydration reaction between a carboxylic acid derivative and a [thiol](#). Thioesters are common intermediates in biochemistry, for example, in acetyl-CoA, malonyl-CoA, acetoacetyl-CoA, and propionyl-CoA. Thioesters are intermediates in several key processes in which ATP is either used or regenerated. Thioesters are involved in the synthesis of all biological esters, including those found in lipids. They also participate in the synthesis of a number of other cellular components, including peptides, fatty acids, sterols, terpenes, and porphyrins. The carbonyl group in thioesters is electrophilic; thus, thioesters and amines combine to give amides:

The protons on the carbon atoms adjacent to the carbonyl group in thioesters are mildly acidic and undergo aldol condensations, a reaction which occurs in the biosynthesis of fatty acids. Thioesters have been proposed to be important for the origin of life, for example, in de Duve's "Thioester World" model. In this model, it is proposed that thioesters could have played the role of ATP. Eventually, thioesters could have served to generate ATP through their ability to support the formation of bonds between phosphate groups.

of Technology, Atlanta, GA, USA

Definition

In organic chemistry, a thiol is a compound that contains the -SH functional group, which is the sulfur analogue of a hydroxyl or alcohol group. The functional group is referred to as either a *thiol group* or a *sulfhydryl group*. Thiols are more traditionally referred to as mercaptans. Thiols and alcohols have similar molecular structure, although the C-S-H bond angle is closer to 90° than the C-O-H bond angle of an alcohol. In the solid or liquid state, the hydrogen bonding between individual thiol groups is weak, the main cohesive force being van der Waals interactions between the polar sulfur centers.

Due to the similar electronegativities of sulfur and hydrogen, thiols are less polar and have a lower dipole moment than the corresponding alcohols. Thiols only weakly hydrogen bond with both water and other thiols. Hence, they have lower boiling points and are less soluble in water and other polar solvents than the corresponding alcohols. Akin to the chemistry of alcohols, thiols form thioethers, thioacetals, and thioesters. Thiols and alcohols are very different

in their reactivity, however, as thiols are easily oxidized and thiolates, the conjugate bases of thiols, are good nucleophiles. Thiolates also form strong complexes with many metal ions.

The important biological amino acid cysteine contains a thiol group. The thiol groups of cysteine residues in polypeptides assist in protein folding by forming disulfide bonds. Thiols in enzyme active sites can form noncovalent bonds with enzyme substrate as well, contributing to catalytic activity. Many important biological cofactors are thiols. The biosynthesis and degradation of fatty acids and related long-chain hydrocarbons are conducted on a scaffold that anchors the growing chain through a thioester derived from the thiol coenzyme A. The biosynthesis of methane is mediated by coenzyme M, 2-mercaptoethyl sulfonic acid.

► [Methanethiol](#) (methyl mercaptan) is the heaviest sulfur-containing molecule that has been detected in interstellar molecular clouds.

Tholins

François Raulin
Faculté des Sciences et Technologie, Université
Paris Est Créteil et Paris Diderot, Creteil, France

Keywords

Khare · Laboratory simulation experiment · Plasma experiment · Refractory organics · Sagan · Solid organic product · Titan's aerosols · Titan's haze

Synonyms

[Complex organic product](#)

Definition

“Tholins” designates the solid refractory organics that are produced during the irradiation of gases or ice mixtures of simple compounds by a variety of energy sources, which are also of astrophysical significance.

History

The word tholins was coined by Carl Sagan and Bishun Khare in the late 1970s (Sagan and Khare [1979](#)), when they realized that in many laboratory experiments, simulating the chemical evolution of astrophysical environments starting from simple organic compounds, nonvolatile complex macromolecular organics were systematically formed. They proposed in particular that tholins play a key role in the organic chemistry of interstellar grains and gas. Since these products often looked like mud or tar, Sagan and Khare decided to call them “tholins,” which comes from the Greek word “tholos,” meaning “muddy” or alternatively “domed.”

Overview

Tholins are produced in a large variety of experiments simulating the complexification of organic matter from simple low molecular weight volatile organics under irradiation by various types of energy flux. Miller-Urey type experiments (Miller [1953](#)) simulating the chemical evolution of the primitive Earth atmosphere produce tholins (“primitive Earth tholins”) which may in part be the precursors of molecules of biological importance such as amino acids and nucleic acid bases obtained in such experiments. “Jovian tholins” are formed during laboratory experiments simulating the chemistry of the atmosphere of Jupiter, and “interstellar tholins” are produced during the experiments simulating the organic chemistry in the interstellar medium.

Tholins, Fig. 1 Titan's tholins experiment (Courtesy: Patrice. Coll): (a) The "PLASMA" experiment is used at LISA (Laboratoire Interuniversitaire des Systèmes Atmosphériques, France) to mimic Titan's atmospheric chemistry. A low pressure (~ 1 hPa) gas mixture of N_2 (98%) and CH_4 (2%) flows continuously through a U-tube

reactor, maintained at low temperature (~ 150 K) and installed in a glove box. Titan tholins are deposited on the wall of the reactor and recovered at the end of the irradiation in an inert atmosphere. (b) Image of these tholins from scanning electron microscopy

The most studied tholins are ► **Titan** tholins (Cable et al. 2012; Raulin et al. 2012), the solid macromolecular product formed during laboratory experiments simulating the chemistry of Titan's atmosphere, usually starting from gas mixtures of N_2 and CH_4 and using electron impact as energy source (Fig. 1). Titan tholins have been assumed to be good laboratory analogues of Titan's actual aerosols. Consequently, several laboratories have developed detailed experiments on these tholins, to get information which could be extrapolated to the particles of Titan's atmosphere. This is essential to facilitate the interpretation of the retrieved data from Titan observations. This includes the measurement of the spectral characteristics of Titan tholins in the visible, IR, and UV; the determination of their index of refraction, of their size, and of their morphology; and the determination of their molecular structure. Since the first work by Sagan's group (Khare et al. 1984, 1986), Titan tholins have been extensively studied. They exhibit quite different properties depending on the experimental conditions used for their production, as shown by their average C/N ratio, which varies from less than 1 to more than 11. Experiments at low pressure and low temperature (PLASMA experiment)

closer to Titan's upper atmosphere conditions (Ramirez et al. 2002; Bernard et al. 2006 and references therein) and using a glove box purged with pure N_2 to sample Titan tholins without oxygen contamination have been developed to provide more representative laboratory analogues of Titan's aerosols. Experiments producing tholins in levitation (PAMPRE experiment) have also been done (Szopa et al. 2006). The influence of the pressure of the starting gas mixture on the elemental composition of the tholins has been systematically studied: depending on the pressure, two different chemical-physical regimes with a transition pressure around 1 mbar (Imanaka et al. 2004 and references therein) seem to occur. In spite of the many studies, the molecular composition of Titan tholins is still poorly known. However, they seem to be made of macromolecules of largely irregular structure, with molecular weight from several hundreds to several tens of thousands of daltons. Their structure includes aliphatic and benzenic hydrocarbon groups, CN, NH_2 , and $C=NH$ groups. Their hydrolysis yields a large variety of amino acids (Khare et al. 1986), even when conducted at low temperatures (Ramirez et al. 2010; Neish et al. 2010). Experiments using VUV irradiation

(from tunable synchrotron radiation) and high-resolution mass spectrometry for molecular analysis have been recently carried out (Imanaka and Smith 2010). Extrapolation of their results to Titan suggests that nitrogenated organic aerosols are formed in Titan's upper atmosphere.

The Ion and Neutral Mass Spectrometer (INMS) on ► [Cassini](#) has detected high molecular weight negative ions in the ionosphere of Titan, which may be linked to the formation of Titan's aerosols and tholins (Waite Jr et al. 2007). Data from the Aerosol Collector and Pyrolyzer (ACP) on the ► [Huygens](#) probe suggest that Titan's aerosols release HCN and NH₃ when pyrolyzed at 600 °C (Israël et al. 2005). Although still debated (Biemann 2006; Israël et al. 2006), this supports the hypothesis that laboratory Titan tholins are similar to Titan's haze particles (Coll et al. 2013).

Threonine

Kensei Kobayashi

Yokohama National University, Yokohama, Japan

Definition

Threonine is one of the protein ► [amino acids](#) whose chemical formula is $\text{HO}_2\text{CCH}(\text{NH}_2)\text{CH}(\text{OH})\text{CH}_3$. Its three-letter symbol is Thr, and its one-letter symbol is T. As in the case of serine, it has a hydroxyl ($-\text{OH}$) group in its side chain, and

it is classified as a polar amino acid. Its molecular weight is 119.12, and its isoelectric point is 6.16. Threonine has two asymmetric carbons (α -carbon and β -carbon) as does isoleucine. Thus, threonine has four stereoisomers: L-threonine, D-threonine, L-*allo*-threonine, and D-*allo*-threonine. Only L-threonine is used in biosynthesis of ► [proteins](#), and it is widely distributed in the biosphere.

Thymine (T)

Shin Miyakawa

Kamagaya, Chiba, Japan

Definition

Thymine ($\text{C}_5\text{H}_6\text{N}_2\text{O}_2$, molecular weight: 126.12) is one of the four nucleic acid bases found in DNA. Thymine has a methyl group ($-\text{CH}_3$) at the 5'-position of the pyrimidine ring. In double-stranded DNA, thymine pairs with adenine via Watson-Crick base pairing with two hydrogen bonds. The half-life of thymine in water is 56 years at 100 °C and 20×10^8 years at 0 °C at pH 7. Thymine has a UV absorption maximum at 265 nm and may dimerize when it is irradiated with ultraviolet light.

Mars exploration · Utopia Planitia · Rover · Orbiter

Definition

Tianwen-1 is the first Chinese mission to the planet Mars. Launched, by a Long March 5 rocket, on July 23, 2020, the spacecraft has been placed on a Martian orbit on February 10, 2021. The lander has separated from the orbiter and landed in *Utopia Planitia* on May 15, 2021. The lander delivered a platform and a rover, Zhurong, on the Martian surface. The rover egressed from the landing platform on May 22, 2021. The orbiter carries seven scientific instruments and the rover six. Two years is the nominal lifetime of the orbiter while the rover has a nominal lifetime of 90 days. ESA, CONAE, FFG, and CNES are the four international partners contributing to the mission.

History

The first Chinese mission to Mars was an orbital probe (Yinghuo) to be delivered to Mars by the Russian mission Phobos-grunt which failed few minutes after the launch in 2011. The mission Tianwen-1 was formally approved in 2016 (Geng et al. 2018) for a launch 4 years later. In parallel, some international cooperation was developed. The European Space Agency supported the telecommunication system during the launch and the travel to Mars; the Argentinian Space Agency (CONAE) hosts a Chinese deep space telecommunication antenna (the only one in the south hemisphere); The Austrian Research Promotion Agency (FFG) cooperates on the

calibration of the magnetometer placed on the orbiter. Under the auspices of the French space agency (CNES), the “Institut de Recherche en Astrophysique et Planétologie” (IRAP) cooperates on the calibration of the Chinese LIBS (Laser-Induced Breakdown Spectroscopy) on the rover, while the “Institut d’Astrophysique Spatiale” (IAS) shares expertise in the characterization of possible landing sites.

Overview

The scientific objectives of Tianwen-1 mission are (i) to map the geological and morphological structures of Mars; (ii) to study the structure of the Martian ground and study the ice water distribution; (iii) to analyze the surface rocks composition; (iv) to collect data on the ionosphere and to characterize the Martian climate and the surface environment; and (v) take measurements of the electromagnetic field and the gravitational field of Mars and study the Martian internal structure.

The spacecraft is composed of an orbiter (mass 3710 kg) (Fig. 1) and a landing module (mass 1300 kg) (Fig. 2).

The orbiter hosts 7 scientific instruments (Yongliao et al. 2021) (Table 1).

The rover hosts six instruments for science (Yongliao et al. 2021) (Table 2).

The orbiter Tianwen-1 and the rover Zhurong resumed operations in October 2021 after a month of radio communication blackout due to the sun conjunction.

During the primary mission, Zhurong traveled around 1300 m, and the mean speed was 10 m/d with a maximum at 20 m/d. While Tianwen-1 orbiter is changing orbit to prepare for a global mapping of Mars, the oldest ESA spacecraft around Mars, → MarsExpress, performed communication tests with the rover. Mars Express is not able to send radio signals receivable by the rover (frequency incompatibility), but it can receive and transmit to the Earth signals from the rover. The rover is not aware of the position of the receiving satellite, and it transmits data without the usual “handshake” between the emitter and the

Tides, Archean

Christoph Heubeck

Institut für Geowissenschaften, Friedrich-Schiller-Universität Jena, Jena, Germany

Keywords

Tides · Archean · Moon · Tidal friction · Tidal range

Definition

Tides are periodic deformations of a planet's solid, liquid, and gaseous substances due to their locally changing gravitational attraction to an orbiting object. This article will limit itself to marine tides on Earth caused by the Moon.

Overview

Tides are highly productive ecologic zones, providing an ideal and variable mix of nutrients, water, and energy for life. Wetting and drying cycles in sandy pore spaces in tidal zones make ideal biochemical laboratories, and the strong abrasive forces provided by rolling sand grains result in high rates of lateral gene transfers between injured or squashed cells. Recent and ancient tidal zones have thus long attracted the attention of biologists, prebiotic chemists, and geneticists. Nevertheless, the dynamics of tidal zones in the deep geologic past are difficult to quantify.

Basic Methodology

Apollo Lunar Laser Ranging since the 1970 has established that the radius of the Moon's orbit about Earth currently grows at a rate of about 3.74 cm/year. However, this rate is considered anomalously high (Kagan 1997; review in Coughenour et al. 2009). If it had been constant and its orbit be reconstructed, the Moon could not have been older than about 2 Ga, at which time it would have reached the ► [Roche limit](#). This conflicts with the established geological age of the Moon of ca. 4.54 Ga. Thus, the lunar recession rate must have been significantly lower at some time in the geologic past. It is safe to say, though, that the Moon must have orbited Earth in a nearer orbit, that its period consequently must have been shorter, and that the gravitational attraction of water to the Moon must have been higher than at present.

The reason for the Moon's spiraling orbit is the gradual transfer of angular momentum from Earth to Moon due to (among other) tidal friction between water and solid Earth, slowing Earth down and transferring its angular momentum to the Moon, a concept which goes back to Kant and Laplace. (If all of that angular momentum was put back into the Earth, it would rotate with a period of only about 4–6 h.) This transfer also reduces the eccentricity and potentially the inclination of Moon's orbit. But how did tidal friction change

through time? This question is almost impossible to answer. Because tidal friction originates mostly where tidal currents move over a solid surface and thus lose energy, which occurs mostly on continental shelves, the past area of shelves and local tidal forces enter the equation (Brosche 1984; Archer 1996b). The shape of ocean basins through time as well as the rate and mode of growth of continental crust, however, which will determine this factor, are a matter of controversy (see, e.g., Kagan 1997). The despinning of Earth by transfer of angular momentum to the Moon slows down Earth's rotation rate, increases the length of the solar day, and reduces the number of tides at a given point per time period (Kvale et al. 1999). However, as Earth's spin rate slows down, so does Moon in its growing orbit about Earth, so that the number of lunar days per month (the synodic month, that is, New Moon to New Moon which largely controls neap–spring cycles) may have changed little; it is presently 29.53 days (see review in Mazumder and Arima 2005). The influence of the Moon on Archean tidal range and frequency is thus difficult to quantify because the determination of absolute Earth–Moon distances and Earth's paleorotational parameters in the distant geological past from tidal rhythmites is ambiguous. This, in turn, is because of the difficulties in determining the absolute (not relative) length of the ancient lunar sidereal month accurately (Mazumder and Arima 2005).

Key Research Findings

Aside by the parameters of celestial mechanics, the global tidal range in the Archean was likely also affected by a number of terrestrial factors:

1. Due to the high heat flow, lithospheric thickness may have been thinner and lithospheric flexural strength reduced. ► **Continents** were on average less capable of supporting high elevations and had an overall lower topography and a higher percentage of wide, low-lying coastal plains.

2. Continents and continental fragments may have been smaller and presented only weak obstacles to the tidal bulges circling Earth. In contrast, today, tidal bulges mostly rotate about amphidromic points in rather isolated ocean basin, driven by the Coriolis force (Archer 1996a).
3. The complete absence of stabilizing vegetation, baffling and dissipating tidal currents, enabled tides to reach farther inland than at present. This may have been aided by an unknown degree of tidal flat sealing by thick and cohesive microbial mats which may have locally reduced the basal friction of in- and outgoing tides.
4. The higher degree of partial asthenospheric melting thickened ► **oceanic crust** so that it floated higher on the ► **asthenosphere**. This displaced water inundated a large proportion of continental margin (“reduced continental freeboard”). The wide shelves thus created are known to favor high tidal ranges, and tidal height may, in fact, increase as open-ocean tides approach a wide, shallow water platform (Klein 1982; Pratt and James 1986).
5. High tides cause embayments and estuaries which in turn amplify the tidal range (funnel effect) when the time required for the tide to move in and out of the basin is close to one of the astronomical tide periods. Open-ocean tides of about 1 m/day may reach up to 16 m/day.

Because the patterns and controls on tidal range at any one location are complex and vary highly even on modern Earth (including topographic geometries, bathymetric changes, astronomical parameters) and because only a tiny fraction of Archean time has been preserved in very few remnants of Archean surface (so-called ► **green-stone belts**), it is unlikely that we will be able to reach valid conclusions about Earth's Archean tides from isolated outcrops; this, of course, does not free geologists from investigating the few occurrences recording ► **Precambrian** tidal signatures.

In attempting to quantify the Archean tidal record, geologists distinguish between tidal bundles (laterally accreted cyclic foreset beds separated by mud laminae) and tidal rhythmites (vertically accreted planar laminae that alternate between coarse- and fine-grained sediments; see review by Longhitano et al. 2012). Both commonly occur in inter- or subtidal depositional environments and show a rhythmic thickness variation because their mode of deposition (e.g., saltating sand interbedded with suspension-settled mud) is primarily determined by current velocity and tidal range. However, the unequivocal recognition and quantitative analysis of Precambrian tidal deposits is fraught with uncertainty. It requires a specific setting with a moderate to significant tidal range, significant accommodation space, high sedimentation rates, significant suspended load, and the general absence of bioturbation (Archer 1996b).

From the Archean, only two such records are published (Eriksson and Simpson 2000; Mueller et al. 2002). Eriksson and Simpson (2000) analyze tidal deposits in the ► **Moodies Group** (ca. 3,225–3,215 Ma) of the ► **Barberton Greenstone Belt** from the thickening and thinning patterns of tidal bundles exposed over ca. 1.2 m thickness of a subaqueous sand bar. They interpret a periodic pattern of 9–10 as reflecting semi-monthly neap–spring–neap cycles (compared to a recent semimonthly periodicity of about 14). However, the syntectonic character of the Moodies Group suggests that the tidal signal may be more influenced by local orogenic conditions rather than by globally operating processes.

Tidal deformation · Tidal dissipation · Tidal locking · Tidal potential · Tides

Definition

Tides are deformations of a ► **planet** or natural satellite caused by periodic variations of the local gravity acceleration as the planet or satellite rotates and revolves in the gravity field of a (disturbing) body. Tidal disturbances of a planet are primarily caused by the Sun and by the planet's satellites. The planet will – in turn – also tidally disturb the satellites. On the Earth, tides are caused by the Sun and the Moon. Marine tides – the tidal deformation of the surface of the oceans – are most obvious and well known. In addition, there are atmospheric pressure variations caused by tidal accelerations and tidal deformations of the

solid planet. Dissipation of tidal deformation energy can be a substantial heat source for planets and satellites and can cause changes in the rotation and orbital parameters.

Overview

The equilibrium surface of a planet depends on the distribution of mass in its interior (interior structure) and its rotation rate. The gravitational and centrifugal forces combine to define an equilibrium surface that the planetary surface would attain were the planet in hydrostatic equilibrium and in empty space. In addition to these internal forces, there may be external forces caused by the gravity of a satellite – such as the ► [Moon](#) on Earth – and/or by the gravity of the primary body about which the planet is orbiting. For the planets of our ► [solar system](#), the latter is the Sun. For the satellites, these bodies are their primary planets such as Earth for the Moon and ► [Jupiter](#) for, e.g., ► [Io](#) and ► [Europa](#). Because the planet-satellite pair is rotating about a common center of mass, the centrifugal force contributes to the tidal force causing tidal deformations to be symmetric (compare Fig. 1) with one bulge roughly pointing toward the disturbing body and a second bulge pointing in the opposite direction. For perfectly elastic or fluid bodies, the bulges would point exactly to and away from the disturbing body.

For real planetary bodies, their viscoelastic rheology causes the tidal deformation to lag behind the disturbance. As a consequence, the tidal bulge will precede the disturbance for a planet that rotates faster than the satellite is orbiting (Fig. 1). In this case, the satellite is above its so-called synchronous ► [orbit](#) (all of the large satellites in the solar system). The bulge will lag behind the disturbance if the satellite orbits faster than the planet rotates. In this case, the satellite is below its synchronous orbit (e.g., ► [Phobos](#) and several small satellites of the giant planets).

In principle, neighboring planets can also have a tidal effect. In the solar system, their gravitational accelerations are small in comparison with those of the Sun and the mutual gravitational attractions between planets and their satellites. However, in some multiplanetary systems (e.g., TRAPPIST-1), the planet-planet tides are expected to play a role comparable with the tides raised by the host star (Lingam and Loeb 2018).

On Earth, the most notable tidal effects are the marine tides with amplitudes of high and low tides, particularly strong in epicontinental seas such as the North Sea. Although atmospheric pressure will vary with the tides, much more pronounced are atmospheric pressure variations caused by the time variation of the solar heating during a solar day. These variations are often termed atmospheric tides (e.g., Lindzen and Chapman 1969), but these are not further considered here.

Tides, Planetary, Fig. 1 Tidal bulge raised on a planet by an orbiting satellite. It is assumed that the planet rotates faster than the satellite orbits the planet. That is, it is assumed that the rotational angular velocity ω exceeds the orbital angular velocity (or mean motion) n . In this

case, tidal dissipation causes the tidal bulge to precede the satellite. The torque exerted by the satellite on the bulge will reduce the planetary rotation rate. The torque exerted by the bulge on the satellite will accelerate the latter and increase the orbital distance

Tidal Potential and Deformation of the Equipotential Surface

In the following, we focus on body tides and start for simplicity with an ideal spherical and fluid planet or satellite and take the disturbing body to be a point mass. The tide-raising potential at any point on the surface of the planet can be cast in terms of a spherical harmonic expansion. Considering the most important term of second order only and assuming rotational symmetry for the planet, we have for the tide-raising potential (compare, e.g., Stacey and Davies 2008)

$$\psi = -\frac{3}{4} \frac{GM r^2}{a^3} \left(\cos 2\theta - \frac{1}{3} \right) \quad (1)$$

In Eq. 1, G is the universal gravitational constant, M the mass of the tide-raising body, a the distance between the center of mass of the planet and of the tide-raising mass, r the radial distance from the center of mass of the planet to the point under consideration, and θ the angular distance between the point under consideration and the line connecting the centers of mass of the planet and the tide-raising body. From Eq. 1, we can conclude that the tidal potential decreases with the third power of the distance to the tide-raising body. We further conclude that the potential is symmetric with respect to a line through the two centers of mass and with respect to a plane that contains the center of mass of the planet and whose normal vector is colinear to the connecting line. Therefore, if the planet rotates much faster than the satellite orbits the planet, the tides will have a period of about half the planetary rotation rate.

The deformation δ of the equipotential surface above the undisturbed surface is

$$\delta = \frac{\psi}{g} = \frac{3}{4} r \frac{M}{m} \left(\frac{r}{a} \right)^3 \left(\cos 2\theta - \frac{1}{3} \right) \quad (2)$$

where m is the mass of the planet. For the lunar tide of the Earth, the peak-to-trough value calculated from Eq. 2 is about half a meter. This is about

twice the value that is actually observed as the peak-to-trough deformation of the solid body of the Earth. Tidal deformations of the solid planetary surface can be measured with tiltmeters or with laser ranging from satellites. The equipotential surface can be tracked with satellites through Doppler ranging and with gravimeters on the planet's surface.

Tidal Love Numbers

As the planet deforms, a further potential Ψ' will be raised that is due to the gravity of the deformed mass. This potential will cause an additional deformation δ' (compare Fig. 2). A.E.H. Love introduced two dimensionless numbers named after him. The first, k , is the ratio Ψ'/Ψ . The second Love number h is defined as the ratio between the height of the body tide above the undisturbed surface and δ . There is a third number, the Shida number l , that gives the ratio of the horizontal component of the deformation of the planetary surface to that of the deforming potential.

For an ideally fluid planet in tidal equilibrium, $k = 3J_2/q$ and $h = 1 + k$, where J_2 is the coefficient of the second-order term of the gravitational potential (see the discussion in ► [Interior Structure](#)) and $q \equiv \omega^2 R_p^2 / Gm$. In addition to already defined quantities, ω is the planetary rotation rate. These Love numbers are usually called the fluid tidal Love numbers k_{2f} and h_{2f} and can be used to constrain models of the interior structure of planets and satellites. For a constant-density planet in hydrostatic equilibrium, $J_2 = 1/2q$, $k_{2f} = 3/2$, and $h_{2f} = 5/2$.

For viscoelastic planets, the Love numbers depend on the rheology and on the internal mass distribution. In particular, the viscoelastic Love number k_2 of a homogeneous planet is defined as

$$k_2 = \frac{3}{2} \frac{1}{1 + \frac{19}{2} \frac{\bar{\mu}}{\rho g R_p}}$$

Tides, Planetary, Fig. 2 Sketch of the tidally deformed surfaces of a planet or satellite. Shown are the undisturbed surface, the tidally deformed surface, the equipotential surface of the gravitational potential Φ plus the tidal disturbance potential Ψ , and the equipotential surface of the sum of the potentials including Ψ' . The latter is the contribution

to the potential of the tidally deformed masses. Also shown are the local heights of the surfaces $h\delta$, δ , and $\delta' = k\delta$. The height of the equipotential surface $\Phi + \Psi + \Psi'$ above the tidally deformed surface is an observable factor and is equal to $(1 + k - h)\delta$. It is called the tidal tilt factor

where $\tilde{\mu}$ is complex rigidity, which defines the viscoelastic behavior, ρ is mean density of the planet, and g is the surface gravity. Because the rheology parameters are temperature and frequency dependent, there is also a dependence on the interior temperature and on the rotation and revolution rates. The rigidity of the mantle rock precludes values of the Love numbers larger than unity for terrestrial planets. For Earth, $h \approx 0.6$, $k \approx 0.3$, and $l \approx 0.04$; for the Moon, the Love numbers are about an order of magnitude smaller.

The tidal Love number h for icy satellites with substantial subsurface oceans decoupling the ice shell from the satellite bulk can be larger than unity. For Europa, for example, Hussmann et al. (2010) obtain $h = 1.172$ and $k = 0.245$ for a model with a 30-km-thick ice layer on top of the ocean.

Tidal Dissipation

Because planets are viscoelastic bodies, tidal deformation is accompanied by dissipation of

deformation energy. This is – potentially – an important heat source in the interiors of planets and satellites. The dissipation rate is often taken to be proportional to the inverse of a dimensionless quality factor Q , with

$$\frac{1}{Q} \equiv \frac{\Delta E}{E} \quad (3)$$

where ΔE is the energy loss per tidal cycle and E is the elastic deformational energy stored in the planet per cycle. An alternative approach takes the Love number k to be a complex number with the imaginary part measuring the dissipation rate (e.g., Spohn 1997). The tidal dissipation rate then depends on the deformation $h\delta$, the period of the forcing τ , and the viscoelastic properties (shear modulus μ and Q) of the planet. To orders of magnitude, we have, following Hubbard (1984),

$$\frac{dE}{dt} \sim \frac{2\pi}{\tau} \frac{4}{3} R_P^3 \frac{\mu}{Q} \left(\frac{h\delta}{R_P} \right)^2 \quad (4)$$

It should be noted that the viscoelastic properties of the planet are usually temperature dependent, potentially leading to feedback between the dissipation rate and internal temperature: An increase in temperature will cause a decrease in Q of solid rock, which will lead to an increase in the dissipation rate and, thereby, to a further increase in temperature. One should be aware, however, that the heat transfer rate will also depend on temperature and may counterbalance the heating. Since Q must be proportional to the mantle rock $\blacktriangleright$ [viscosity](#), the heat transfer rate can increase with increasing temperature, potentially resulting in a stable equilibrium between tidal heating and heat transfer. Such equilibrium states have been described by, e.g., Fischer and Spohn (1990) and Spohn (1997) for Io and by Hussmann and Spohn (2004) for Io and Europa. The decrease in Q with increasing temperature can also be stopped by partial melting of the mantle or by a transition to a less dissipative low-viscosity state (Henning et al. 2009).

Tidal dissipation rates can be substantial. Io, a satellite of Jupiter of approximately the size of the Moon, has a surface heat flow of 2 W m^{-2} (or 80 TW, e.g., Spencer et al. 2000), 20 times the Earth's heat flow per unit area and about 100 times the lunar value, together with an enormous volcanic activity. It is universally agreed that the activity is due to tidal heating. It should be noted, however, that the large dissipation rate is maintained by an orbital resonance (the $\blacktriangleright$ [Laplace resonance](#)) with the two other Jovian satellites Europa and $\blacktriangleright$ [Ganymede](#). Europa may also experience tidal dissipation which may be contributing to its energy balance and help keep a liquid ocean beneath the near-surface ice shell (e.g., Hussmann and Spohn 2004). The vapor plumes observed at the Saturnian satellite $\blacktriangleright$ [Enceladus](#) have also been explained as being caused by tidal dissipation (Tobie et al. 2008). On Earth, a significant part of the total dissipation of about 2 TW occurs at the bottom of shallow and deep oceans (Lambeck 1977; Egbert and Ray 2000). This effect defies a simple treatment because of the complicated ocean bottom topography and is estimated using Earth observation satellite data and computer simulations.

Tidal Dissipation and Orbital and Rotational Evolution

Tidal dissipation will not come for free. The power that is dissipated in a planet or satellite will be taken from the rotational and orbital energies. A thorough discussion of the interactions must be based on conservation of energy and $\blacktriangleright$ [angular momentum](#) considerations and may have to include the temperatures of the interiors and the temperature dependence of the viscoelasticity (e.g., Spohn 1997). Tidal dissipation in the planet reduces its rotation rate and increases the orbital distance of the satellite and the $\blacktriangleright$ [eccentricity](#) (and potentially the inclination) of its $\blacktriangleright$ [orbit](#) (compare Fig. 1) if the planet rotates faster than the satellite orbits. Tidal dissipation in the satellite will decrease the satellite's rotation rate and reduce the rate of orbital expansion and the orbital eccentricity. This is why most major satellites are locked in a 1:1 spin-orbit coupling. But how can there be tidal dissipation in a satellite with 1:1 spin-orbit coupling? The answer lies with the orbital eccentricity. If a satellite were on a circular orbit with a 1:1 spin-orbit coupling, the tidal deformation would be a constant bulge that would point toward the planet. If the orbit is eccentric, the satellite will move toward the planet as it approaches pericenter and away from the planet as it approaches apocenter. Because of the strong dependence of the tidal disturbance potential (Eq. 1) on the distance, the tidal deformation will increase and decrease periodically. As the orbital velocity varies along the eccentric orbit with a maximum at pericenter and a minimum at apocenter, the difference between the orbital and the rotational speed will oscillate about zero as will the tidal bulge oscillate about its average orientation. The energy will have to come from the orbital energy in this case, and as a consequence of energy and angular momentum conservation, the semimajor axis and the eccentricity will decline.

Tidal dissipation is thus subject to a rule qualitatively similar to the Lenz rule of induction: The dissipation acts such that it will reduce its origin. How rapidly are eccentricities damped and rotations synchronized with orbital periods? The answer will depend largely on the viscoelastic

properties of the planet and satellite, their masses and radii, and the distance between the two. For a satellite orbiting on a circular orbit ($e = 0$), the time rate of change of the difference between the satellite's rotation angular velocity ω_S and the orbital angular velocity of the satellite n is (Peale and Canup 2015)

$$\begin{aligned} \frac{1}{(\omega_S - n)} \frac{d(\omega_S - n)}{dt} &= -\frac{15}{2} \frac{k_S}{Q_S} \frac{m_P}{m_S} \left(\frac{R_S}{a}\right)^3 n \\ &= -\frac{1}{\tau_R} \end{aligned} \quad (5)$$

where the subscript S refers to the satellite and the subscript P to the planet. The solution of Eq. 5 indicates that $(\omega_S - n)$ decays exponentially with a decay time equal to τ_R . For the satellites of Jupiter, the decay time is of the order of thousands to some 10,000 years but could be billions of years for a gaseous exoplanet orbiting a star. The damping of the eccentricity e_S of a satellite orbit follows, simplified from Peale and Canup (2015):

$$\begin{aligned} \frac{1}{e_S} \frac{de_S}{dt} &= -\frac{21}{2} \frac{k_S}{Q_S} \frac{m_P}{m_S} \left(\frac{R_S}{a}\right)^5 n \\ &= \frac{21}{15} \left(\frac{R_S}{a}\right)^2 \frac{1}{\tau_R} \end{aligned} \quad (6)$$

where again the subscript S refers to the satellite and the subscript P to the planet. In the above form, Eq. 6 should be applicable as long as the mass of the primary is much larger than the mass of the satellite. The time constant for the exponential damping of the satellite eccentricity τ_e is by a factor of roughly $(a/R_S)^2$ larger (since $R_S/a \ll 1$) than the damping of the rotation rate. For satellite-planet pairs like Io-Jupiter or Europa-Jupiter, this translates into damping times of the order of 10–100 Ma. However, in the Jupiter satellite system, the Laplace resonance between the Galilean satellites works against the decrease of the orbital eccentricities.

All major satellites in the solar system are tidally locked in a 1:1 spin-orbit resonance (also called synchronous rotation). However, the rotation rates of planets with a high orbital

eccentricity, such as that of planet [Mercury](#) with $e = 0.2$, are naturally driven to higher-order spin-orbit resonances. In the case of Mercury, the current rotation state is a 3:2 spin-orbit resonance, in which the planet turns around its spin axis three times during two orbital periods. Low-mass exoplanets with viscoelastic mantles and high orbital eccentricities might be locked in 2:1, 5:2, or even higher spin-orbit resonances, depending on the exact eccentricity, tidal frequency, interior properties, permanent deformation of the planet, and past rotational and orbital evolution (e.g., Ferraz-Mello 2015). On the other hand, hot Jupiters, or gaseous exoplanets orbiting close to their host star, might either be locked in synchronous rotation (on a circular orbit, $e = 0$), or they could undergo so-called pseudo-synchronous rotation (if $e > 0$). In this spin state, the stationary rotation is faster than the mean motion and the exact rate depends purely on the eccentricity. Again, the time required for evolving into the tidal locking strongly depends on the planet's distance from the host star. In addition to the effect of the eccentricity, the stable spin state also depends on the axial tilt of the moon or planet, with high axial tilts enabling a higher-order spin-orbit resonance even on circular orbits (Boué et al. 2016).

Tides and Planetary Habitability

Strong tidal dissipation and the resulting orbital and rotational evolution may also present a constraint on planetary habitability. A moon or a planet is considered habitable if it enables the emergence or existence of life: i.e., if it can support liquid water on the surface or in the subsurface and its environment is stable.

Tides can affect the habitability of moons and (exo-)planets in both positive and negative ways. First, the tidal heating may help to maintain subsurface liquid oceans on icy worlds or to support the formation of a secondary atmosphere on massive exoplanets (Noack et al. 2017). On the other hand, the excessive volcanic activity driven by the increased interior heating rate may transform the planet to an inferno. Second, the tidal evolution of

axial tilt and the planet's spin rate may have profound effects on the stability of the climate. A planet with aligned spin axis, orbiting close to its host star on a circular or almost circular orbit, is inevitably driven by the tidal forces to synchronous rotation (e.g., Boué et al. 2016). Once in this spin state, the planet experiences eternal day on the hemisphere facing the star, while the other hemisphere is immersed in eternal night. The continuous day-night dichotomy leads to great differences in surface temperature and atmospheric pressure, which may eventually lead to a destabilization of the climate (e.g., Kite et al. 2011). Finally, the tidally induced orbital evolution may transform a previously habitable planet to a dead world simply by driving its orbit too close to the host star and triggering a runaway greenhouse effect. In other cases, however, the decrease in the semi-major axis and the eccentricity can also enliven a previously uninhabitable planet into the circumstellar **▶ habitable zone** (Barnes et al. 2009).

All the tidal effects mentioned above are particularly relevant to potentially habitable exoplanets orbiting low-mass (M-type) stars, for which the habitable zone lies at short astero-centric distances. The influence of tides has also been discussed in connection to the habitability of moons that are, otherwise, orbiting planets at large semi-major axes outside the conventional habitable zone. If these moons are locked in mean-motion resonances (such as the Laplace resonance), they can maintain nonzero orbital eccentricities and remain tidally active – and potentially habitable – for long periods of time.

Time Series

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

A time series is a sequence of data points, measured at successive regular time intervals, in the case of astronomy generally over long periods of several months to several years. Time series are used in astronomy to record position or brightness of celestial objects in order to detect, for example, motion or periodicity. For instance, planetary transits can be detected by analyzing time series of stellar brightness measurements and looking for tiny periodic dips in the signal.

Tirez Lagoon System

Felipe Gómez

Keywords

Earth analogues · Mars · Europa Moon

Definition

Located in Spain, Tirez Lagoon system is an ecological area composed of seven small salty lakes. These lakes are very diverse in depth but some of them have a depth of 20 meters. This area is located at a distance of 110 km from Madrid (central Spain). The thermal range varies between $-0,4^{\circ}\text{C}$ and $25,8^{\circ}\text{C}$. The site is located near the town of Villacañas. The most representative lagoon in the system is Tirez Lake. It is a dry surface composed by NaCl which is a chloride salt. Analyzing the salts deposits in Tirez Lake would help constraining the phase development of the liquid chemical composition and the crystallization of various chloride salts. This lake has also a biodiversity (e.g., halophilic bacteria) which tolerates the extreme environment of the lake.

Overview

The astrobiological interest of Tirez systems is due to the fact that aqueous minerals and evaporites have been widely detected on the surface of Mars and are a major evidence of the past presence of liquid water on the Martian surface. At the same time, Tirez system is a well-studied Earth analogue for the Jupiter's moon Europa (Prieto-Ballesteros et al. 2003). They offer a paleo-environmental record of their geological formation and chemical conditions, as well as subsequent modification and alteration processes. The evaporite minerals (i.e., sulfates and chloride salts) have been mainly detected stratigraphically

on top of the aqueous minerals (i.e., phyllosilicates), which suggest their posterior formation. As both these mineral groups require liquid water for their formation, and that each group is a result of different chemical conditions, this stratigraphic relation points to a major change of surface chemical environment. Moreover, it reveals various liquid water activities on the surface of Mars occurring in repetitive and probably episodic phases.

Phyllosilicates have been hypothesized as a major element in the chemical evolution resulting in the origin of life on Earth, because of their ability to concentrate and catalyze complex organic molecules, and thus to protect against UV radiation they have a preservation capacity. Therefore, the phyllosilicate-bearing deposits on Mars have been investigated as a potential target for the investigation of past habitable sites. Evaporites, on the other hand, can also preserve traces of life, e.g., salt crystals which can preserve amino acids for a few million year and biosignatures found in sedimentary evaporitic layers (e.g., in dry Rio Tinto). Analogue studies in the Atacama desert show that even highly saline environments may offer temporary habitable conditions to certain types of bacteria.

Evaporite deposits represent significant sinks of mobile cations (e.g., Ca, N, Mg, and Fe) and anions (e.g., those of C, N, S, and Cl) which are partly composing the Martian surface and upper crust. The salt-rich deposits appear to be the product of last-stage water activities on the Martian surface, as it is suggested by their undegraded, uneroded, and unaltered appearance. Hence, where phyllosilicate-rich materials are covered and preserved by evaporites, it may be a prime location for search for traces of life on Mars, and in situ rover measurements. In addition, understanding the formation mechanism, conditions, and timeframe of evaporites would highly increase our knowledge about the past geological events of Mars, and would constrain the history of surface liquid water.

The microbial biodiversity of Tirez athalassohaline (saline aquatic environment with ionic proportions quite different from the dissolved salts in seawater) environments has been studied (Montoya et al. 2013). Microbial

populations present in the water column and the sediments reported the presence of algae and *Cyanobacteria* as the main photosynthetic primary producers identified in this natural environment in the rainy season. Others microbes were identified in the high salt concentrated solutions as dinoflagelates and filamentous fungi. The most abundant phylotype in water and sediments were *Proteobacteria*, mainly *Gamma*- and *Alphaproteobacteria* classes. *Firmicutes* and *Actinobacteria* were isolated from Tirez brines and sediment samples. Halophilic sulfate reducing *Deltaproteobacteria* were also detected (*Desulfohalobium*) (Montoya et al. 2013).

This system is the appropriated environment for the following research:

- (1) To investigate various evaporite minerals precipitation mechanism and their environment in a comparable analogue site to the Martian conditions. This helps us to understand the chemical environment needed for precipitation of each mineral.

In addition to the chemical composition of the brine liquid water, further investigation of the evaporite samples in the lab would allow us to compare the remotely sensed spectroscopical data from the surface of Mars with our in situ measurements, and therefore better interpreting those data.

- (2) To analyze the paleo-evaporitic deposits and their chemical exchange, alteration and preservation conditions. Understanding how the paleo-evaporite deposits have been altered or preserved would hint to whether this material could have hosted a local habitable environment, even though for a short time.
- (3) Stratigraphical relation within a deposit, and its comparison with Mars to understand whether different atmospheric condition and volatile would affect the sequence of minerals precipitation.
- (4) Comparing alkaline and acidic environments with the goal of identifying which condition is more likely to have formed on the Martian surface during the evaporites formation.
- (5) To assess the impact of a hyper saline and hyper arid area on the preservation of the past life forms.

Definition

Titan, Saturn's moon, is the second largest and only satellite of the solar system having a dense atmosphere composed essentially of dinitrogen (~97%) and methane (~2%). These two molecules give rise to a host of organic compounds, rendering Titan one of the most astrobiologically interesting bodies. In addition, Titan is subject to the effects of seasons and meteorology, shaping the geomorphology of the surface, with unique hydrocarbon liquid bodies and other terrestrial-like features (dunes, channels, mountains). With these properties and the probable existence of an internal liquid water ocean, Titan is a very promising Earth analog which can inform us about the emergence and evolution of life.

Introduction

Astrobiology, the study of life in the universe, is not only the study of the origins, distribution, and evolution of life in the whole universe but also that of structures and processes related to life and the study of the destiny of life. It thus includes the question of the origins of life on Earth and elsewhere, as well as the search for extraterrestrial life, but also the search for organic compounds and the study of organic chemistry and in particular prebiotic-like chemistry in extraterrestrial environments. It is generally considered that life arose on Earth from a long chemical evolution, implying three main ingredients: liquid water, carbonaceous matter, and energy. Extraterrestrial bodies where these ingredients are or have been present are thus of astrobiological interest. They can be classified into two main categories.

There are planetary bodies where (extinct or extant) life may be present and there are bodies where a complex organic chemistry is taking place. Titan falls in the second category and is unique in the Solar System with its extensive atmosphere made mostly of N₂ (~97% in mixing ratio), with a column density 10 times that of Earth's (Fig. 1), and possessing a rich organic

Titan, Fig. 1 Titan's atmosphere – an active place where methane molecules are being broken apart by solar ultraviolet light and the by-products combine to form complex organic compounds. Titan's upper atmosphere observed with the Cassini spacecraft wide-angle camera using red, green, and blue spectral filters which were combined to create this natural color view. The images were obtained at a distance of approximately 9,500 km from Titan on March 31, 2005. The image scale is approximately 400 m per pixel. The haze preferentially scatters blue and ultraviolet wavelengths of light, making its complex layered structure more easily visible at the shorter wavelengths used in this image. (Credit: NASA/JPL/Space Science Institute.). Upper right insert: The glow of Titan's extensive atmosphere shines in false colors in this view acquired by the Cassini VIMS during the July 2, 2004, flyby. While flying over the terminator, where Titan's day and night meet, both the dayside and nightsides are seen at various wavelengths. In these views of the crescent moon, the sunlit side is on the left and the nightside on the right. The blue image shows the sunlit crescent as observed at a wavelength that pierces

through the thick atmosphere to show only the surface. This image is much smaller than the other three images to the right, because it does not show any atmospheric affects. In contrast, the green image (taken at $3.3\ \mu\text{m}$) shows the immense size of Titan's atmosphere manifested in the fluorescent glow of methane gas, which extends over 700 km above the surface. The red image shows that Titan also glows at night, the moon glowing out to more than 200 km in altitude, indicating carbon monoxide emission at the $4.7\ \mu\text{m}$ produced in Titan's relatively warm stratosphere. The multicolor image on the far right combines the three previous images into one composite. Here it is seen that the carbon monoxide glow extends over the dayside as well, producing the yellow layer observed on the left. This is because the two glows, one from methane (green) and carbon monoxide (red), mix together to form yellow in this multicolor composite. Titan's surface is indicated by the circle. Titan's surface appears purple due to the mixing of the blue and red surface images. (Courtesy: NASA/JPL/University of Arizona)

chemistry thanks to the second most abundant constituent, methane (about 1.4% in the stratosphere, 5% on the surface).

Discovered in 1655 by Christiaan Huygens, Titan is the largest satellite of Saturn and the second in the solar system by the size of its solid body (5150 km in diameter). The period of rotation of Titan around the Sun is that of Saturn, 29.5 years. Titan, like Saturn, with an obliquity of 27° , has seasons, each of which lasts

more than 7 terrestrial years. Moreover, Titan revolves around Saturn within 16 Earth-days, with an almost synchronous rotation. Thus Titan's solid surface rotates very slowly. However, due to strong zonal winds (Bird et al. 2005; Lorenz et al. 2008a), Titan's atmosphere presents a super-rotation. Titan's mean distance to the Sun is that of Saturn – about 9.5 astronomical units (AU). This corresponds to a received solar flux at the top of its atmosphere just

slightly higher than 1% of the flux at the Earth. In addition, Titan is far enough from the giant planet (about 20 saturnian radii) to avoid interactions with the rings. However, Titan is close enough to Saturn to allow its atmosphere to interact with the electrons of the magnetosphere of Saturn. This plays a key role, together with the solar photons, in Titan's chemical evolution.

As said above, Titan's atmosphere is mainly composed of dinitrogen and methane. Their dissociation and further chemical evolution, produces a whole host of organic molecules (hydrocarbons like ethane, acetylene, and propane, and nitriles like hydrogen cyanide, acetonitrile, cyanoacetylene, etc.), some of which are of prebiotic interest (like HCN). On the surface, morphological features very similar to the Earth's can be found but made of different materials than on our own planet. With an environment very rich in organics, Titan, along with comets, is thus often considered as one of the best targets to search for prebiotic chemistry at a full planetary scale and is even considered as a possible habitat for extraterrestrial life. More importantly, our understanding of the origin of life on Earth could greatly benefit from studying Titan, where the low solar influx, the composition of the atmosphere, and the possible presence of an internal water ocean, give us the opportunity to study on a planetary scale the conditions prevailing in a primitive Earth.

After 6 years of close observations by remote sensing and in situ instruments on board the Cassini-Huygens mission (see entry "[► Cassini-Huygens Space Mission](#)"), Titan does not appear anymore solely like a frozen primitive Earth, but like an evolving planet, geologically active, with cryovolcanism, aeolian erosion, clouds and precipitations, and a methane cycle very similar to the water cycle on Earth (Coustenis and Taylor 2008; Lorenz and Mitton 2008; Brown et al. 2010; Lebreton et al. 2008; Raulin et al. 2008; and the papers in Nature, 2005). The organic chemistry is found on Titan all the way from the upper atmosphere to the surface and possibly the interior, indicating close exchanges between the different elements.

Cassini and Huygens observations have confirmed the structure of the low atmosphere,

determined by Voyager, provided more precise vertical profiles in stratosphere and troposphere, and obtained information in the higher atmospheric zones. The equatorial surface temperature and pressure measured by HASI (Fulchignoni et al. 2005) are respectively 93.65 ± 0.25 K and 1.467 ± 1 hPa. Due to its low surface temperature, Titan's atmosphere near the surface is about 4.5 times denser than the Earth. Moreover, surface temperatures measurements by the Composite Infrared Spectrometer (CIRS, Jennings et al. 2009) show temperatures 3 or 4 degrees lower at the poles relative to that at the equator, where Huygens landed.

Another discovery of tremendous importance for astrobiology by the Cassini-Huygens mission are the large plumes ejected from Enceladus (see entry "[► Enceladus](#)"), mainly made of water vapor and ice and which include organic compounds (Dougherty et al. 2009; McKay et al. 2014). This strongly suggests the potential presence of a complex organic chemistry going in the interior of this small satellite, in the presence of liquid water.

What is the level of complexity which has been reached by the organic chemistry in Titan and Enceladus? What are the habitability potentialities in the Kronian environment, in particular for Titan? Such are the questions that further exploration of Titan (and Enceladus) will need to answer in the future (Brown et al. 2009).

An Astrobiological Environment

Retracing the processes which allowed for the emergence of life on Earth around 4 billion years ago is a difficult challenge. Our planet has drastically evolved since that time and most of the traces of what were the environmental conditions at that time have been erased. It is thus crucial for astrobiologists to find extraterrestrial locales with similarities to our planet. This will provide a way to study some of the processes which occurred on the primitive Earth, when prebiotic chemistry was active, in the present time.

Titan is an indeed a very complex world much as our own planet (Fig. 2). It is the only one we

Titan, Fig. 2 Schematic illustration of the connections between Titan's interior, surface, atmosphere, and cosmic environment. Images show lakes at north and south poles, mid-latitude terrains with dunes, and fluvial features

carved in the ice crust. Based on data from Cassini VIMS, Radar and Huygens DISR. (Features not presented to scale.) (From Reh et al. (2009))

know of today, beyond our own planet, not only to possess a thick nitrogen-based atmosphere but also a geologically complex active surface including lakes with organic deposits (Raulin 2008) and quite likely a subsurface ocean (Lorenz et al. 2008b; Béghin et al. 2009). The physical processes within this world beg for further close-up investigation in order to better understand the processes also on Earth. The Cassini-Huygens mission has indeed revealed the essential details of the organic and methane hydrologic cycles that we see today on Titan (Brown et al. 2009; Lebreton et al. 2008; Raulin et al. 2008).

Titan's Atmosphere and Surface Hosting a Complex Prebiotic Chemistry

As first shown from ground-based, Voyager and Infrared Space Observatory (ISO) observations, Titan's atmosphere is a chemical factory initiating the formation of complex positive and negative ions in the high thermosphere as a consequence of magnetospheric-ionospheric-atmospheric interactions involving solar EUV, UV radiation, energetic ions, and electrons. In the neutral atmosphere, CH_4 chemistry is coupled with N_2 chemistry producing the formation of many organics in gas and particulate phase: hydrocarbons, nitriles and complex refractory organics. Several photochemical models describing the chemical and physical pathways involved in the chemical evolution of the atmosphere of Titan and estimating the resulting vertical concentration profiles of the different involved molecules have been published for the last 30 years. Based on these models, the cycling of volatile chemicals starts with the dissociation of N_2 and CH_4 through electron, photon impacts, and cosmic rays deeper in Titan's atmosphere. The primary processes allow the formation of C_2H_2 and HCN in the high atmosphere (Figs. 2, 3). These molecules play a key role in the general chemical scheme; once they are formed, they diffuse down to the lower levels where they allow the formation of higher hydrocarbons and nitriles. Additional CH_4 dissociation probably also occurs in the low stratosphere through photocatalytic processes

involving C_2H_2 and polyynes. The end products of the chemical evolution of the methane in the atmosphere are complex refractory organic compounds and ethane (Raulin et al. 2012).

The origin of Titan's atmosphere as such is still a mystery in many aspects; both the Cassini INMS and the Huygens GCMS measured argon in the atmosphere, with the latter obtaining values for both primordial ^{36}Ar and radiogenic ^{40}Ar (Fig. 8). The low value of the former relative to atmospheric N_2 is indirect evidence that Titan acquired its nitrogen originally in the form of ammonia, while the presence of the latter suggests Titan has experienced substantial outgassing over its history (Niemann et al. 2005, 2010). Neon has been tentatively identified by Huygens GCMS, but krypton and xenon have not yet been detected on Titan (Niemann et al. 2010). The presence or absence of krypton and xenon is crucial to constraining the origin of methane as either a primordial gas or one manufactured from carbon dioxide deep in Titan's interior (Atreya et al. 2006). The latter question is not solved today.

The direct analysis of the ionosphere by the Ion and Neutral Mass Spectrometer (INSM) instrument during the low altitude Cassini flybys of Titan shows the presence of many organic species at detectable levels, in spite of the very high altitude (1100–1300 km). Extrapolation of the INMS measurements (limited to mass up to 100 Daltons) and of CAPS data strongly suggests that high molecular weight species (up to several 1000 Daltons) may be present in the ionosphere (Waite et al. 2007). These observations open a fully new vision of the organic processes occurring in Titan's atmosphere, with a strong implication of the ionospheric chemistry in the formation of complex organic compounds in Titan's environment (Fig. 2), which was not envisaged before. These compounds are detectable in solar and stellar UV occultations and initiate the process of haze formation (Waite et al. 2007) to finally condense out starting at ~950 km (Fig. 3). As the haze particles fall through the atmosphere and grow, they become detectable with imaging systems such as the Cassini/Imaging SubSystem (ISS) at ~500 km altitude and are ubiquitous throughout the stratosphere (Porco et al. 2005).

Titan, Fig. 3 The process of tholin formation in Titan's upper atmosphere (Waite et al. 2007). (Credit: H. Waite/Southwest Research Institute)

They are strong absorbers of solar UV and visible radiation and play a fundamental role in heating Titan's stratosphere and driving wind systems in the middle atmosphere, much as ozone does in the Earth's middle atmosphere.

Experiments that simulate the reactions taking place in Titan's atmosphere produce refractory organics, usually named tholins. Tholins represent laboratory analogues of Titan's aerosols and are useful to interpret many observational data which require information on the aerosols. As laboratory analogues of Titan's atmospheric particles, they also allow the study of the aerosols behavior in Titan's condition with the tools available in the laboratory (see for instance, Cable et al. 2012). Several organic compounds

have already been detected in Titan's stratosphere (Waite et al. 2007; Coustenis et al. 2010). The list includes hydrocarbons (both with saturated and unsaturated chains) and nitrogen-containing organic compounds, exclusively nitriles, as expected from laboratory simulation experiments. Since the Cassini arrival in the Saturn system, the presence of water vapor and benzene has been unambiguously confirmed by the CIRS instrument.

On Titan, methane can exist as a gas, liquid, and solid. Methane is dissociated irreversibly to produce a host of various gases such as hydrocarbons (e.g., C_2H_6 and C_2H_2) and nitriles (e.g., HCN and HC_3N), from the coupled nitrogen chemistry, that are detected in the stratosphere

(between 70 and 500 km in altitude) by CIRS for instance (Coustenis et al. 2010). Playing a role similar to that of water on the Earth, methane is cycled between the atmosphere, surface, and the interior. Cloud systems, the size of terrestrial hurricanes (~up to 1000 km across), appear occasionally, while smaller transient systems form on a daily basis (Porco et al. 2005). The smaller clouds dissipate quickly suggesting the presence of precipitation, carving out the fluvial features that cover much of the equatorial landscape and are common also in the vicinity of lakes seen in the northern polar regions (Lorenz et al. 2008b). Titan's atmospheric methane may be supplemented by high latitude lakes and seas of methane and ethane, which over time cycle methane back into the atmosphere where it rains out, creating fluvial erosion over a wide range of latitudes, as suggested by the many observed clouds (Fig. 4).

Eventually, these complex organic molecules are deposited on Titan's surface in large quantities, where data from instruments on board Cassini and Huygens hint at their existence. Hence the upper thermosphere is linked

intimately with the surface and the intervening atmosphere. In spite of the low surface temperature, the organics reaching the surface are probably evolving once in contact with water ice and may form organic molecules of biological interest.

Surprisingly, the Huygens Gas Chromatograph Mass Spectrometer (GCMS) on board Huygens has not detected a large variety of organic compounds in the low atmosphere. The mass spectra collected during the descent show that the medium and low stratosphere and the troposphere are poor in volatile organic species, with the exception of methane (Niemann et al. 2005, 2010, Fig. 5). Condensation of these species on the aerosol particles is a probable explanation for these atmospheric characteristics. These particles, for which no direct data on the chemical composition were available before, have been analyzed by the Aerosol Collector Pyrolyzer (ACP) instrument. ACP results show that the aerosol particles are made of refractory organics which release HCN and NH_3 during pyrolysis (Israël et al. 2005). This supports the tholin hypothesis (Coll et al. 2013). It supposes that the

Titan, Fig. 4 Titan clouds as observed with the Cassini cameras (Porco et al. 2005). (Credit: NASA/JPL/Space Science Institute)

Titan, Fig. 5 Mass spectra from Huygens/GCMS at various altitudes (Niemann et al. 2005). These sample-averaged spectra show the ion count rates per second as a function of unit charge (m/z), either at 120–130 km (upper panel) or at 75–77 km in the rare gas cell (middle panel) or at the surface (bottom panel). In the latter case, a surge of methane and ethane was detected shortly after the probe

impact, indicating an evaporation of volatiles from the surface that was being heated by the probe itself. Furthermore, the very presence of Argon may indicate some geological activity on Titan that would transport Ar from the interior through liquid then solids layers, another clue toward the explanation of the methane replenishment in the atmosphere

complex organics made of C, H and N, atoms, formed when simulating Titan's atmosphere chemistry, and called Titan's tholins, are analogues of the material constituting Titan's aerosols. From these new and first in situ measurement data, it seems very likely that the aerosol particles

are made of a refractory organic nucleus, covered with condensed volatile compounds.

However, the nature and abundances of the condensates have not been measured. Even more important for astrobiology, neither the elemental composition nor the molecular structure of the

refractory part of the aerosols has been determined. The potential chirality of its complex organic part is unknown.

Since 2004, the Cassini-Huygens mission has been providing essential information on Titan. The Cassini orbiter offers global-scale mapping of Titan at moderate spatial resolution (hundreds of meters to kilometers) with potential temporal and spatial variations. The Huygens probe provides very detailed information of one particular location of Titan. The Cassini mission ended in September 2017 with the plunge of the spacecraft into Saturn, after several orbits between the planet and the rings which provided a whole new set of data so that the analysis of the Cassini observations will continue for many years. Those already exploited have revealed a new vision of Titan. The first images of Titan taken by the Cassini instruments have shown a very diversified surface (Fig. 6), with bright and darks zones, and terrains of various morphologies (Porco et al. 2005; Elachi et al. 2005; McCord et al. 2009; Lunine et al. 2008). At higher resolution fluvial, lacustrine, and aeolian processes appear to have shaped the surface as they have on our own planet.

Radar-bright channels (probably methane-wet riverbeds strewn with water ice cobbles like what

was seen at the Huygens landing site) have been observed at low and mid-latitudes, while channels incised to depths of several hundred meters are seen elsewhere, and at high latitudes radar-dark, meandering channels are seen that suggest a lower-energy environment where deposition of fine-grained sediment occurs (Soderblom et al. 2007a; Lorenz et al. 2008b). Radar and near-infrared imagery has revealed channels on much larger scales than those seen by Huygens (Soderblom et al. 2007b; Lorenz et al. 2008b).

Furthermore, since July 2006, we have proof of the existence of exposed open liquid bodies (hydrocarbon lakes or seas) near Titan's north pole (Stofan et al. 2007). Other small lakes exist more to the South, like the Ontario Lacus. The Cassini data have allowed a detailed description of these lakes and their properties, including their main composition –methane and ethane – and surprising transient features (Hofgartner et al. 2016; Le Gall et al. 2016; Hayes et al. 2017; Mastrogiuseppe et al. 2018).

The liquid bodies are one of the main astrobiological aspects of Titan. Cassini's cameras (ISS) have allowed scientists to compile a nearly global surface map and to monitor the surface and atmosphere for activity. Since the detection

Titan, Fig. 6 Titan's surface as observed by Cassini-Huygens, with zooms into surface areas of particular interest, showing possible cryovolcanoes, mountain ranges,

dunes, craters, the fluvial systems, and riverbeds at the Huygens landing site and the lakes in the North. (Credit: NASA/ESA/JPL/LPGN/CICLOPS)

of hydrocarbon lakes similar to those later detected at Titan's North Pole. Intriguingly, repeated south-polar imaging by ISS revealed differences consistent with ponding of hydrocarbon liquids on the surface due to precipitation from a large storm. ISS images of high northern latitudes illustrate the full extents ($>500,000 \text{ km}^2$) of hydrocarbon seas, also observed by Cassini's RADAR. These observations demonstrate dynamic processes at work on Titan and indicate that the poles harbor liquid-hydrocarbon reservoirs, the extents of which differ from pole to pole and which may be coupled to seasonally varying circulation (Turtle et al. 2009).

Other astrobiological aspects are related to the presence of a complex organic chemistry in the environments of the satellite and the question of potential habitability. We also need to consider the addition of water and oxygen ions into Titan's atmosphere from magnetospheric sources which can be traced to Enceladus' observed plumes. The oxygen will primarily be locked up in CO and CO_2 and water will freeze out. Could this water-oxygen compounds then be locked up into aerosols where they form which could be the ionosphere and/or the ionization layers at $\sim 80 \text{ km}$ where the cosmic rays deposit most of their energy.

Potential Habitat

All the ingredients which are supposed to be necessary for life to appear and even develop – liquid water, organic matter, and energy – seem present on Titan at different levels, the atmosphere, the surface, and the interior with opportunities for exchanges and interactions between them.

With the current picture of Titan's organic chemistry, the chemical evolution of the main atmospheric constituents – dinitrogen and methane – produces mainly ethane which accumulates on the surface or the near subsurface, eventually dissolved in methane-ethane lakes and seas, and complex refractory organics which accumulates on the surface, together with condensed volatile organic compounds such as HCN and benzene (Fig. 2).

Simulations of Titan's atmosphere in the laboratory indicated that complex organic chemicals (even larger than the ones found today) could be produced on Titan from reactions taking place in the upper atmosphere where scientists working with Cassini data identified the presence of carbon chain anions (Desai et al. 2017), similar to those existing in the interstellar medium, thus providing clues as to the formation and distribution of organic material throughout the universe. Furthermore, it has been shown in experimental work simulating Titan's atmosphere and without liquid water, that in the presence of energy sources, many prebiotic compounds and even five nucleotide bases, the building blocks of DNA and RNA, were formed along with amino acids, all of which elements are the building blocks of living organisms on Earth. Observations with ALMA showed the presence in Titan's atmosphere of acrylonitrile or vinyl cyanide (Palmer et al. 2017), a molecule which is involved in the formation of azotozomes proposed as membrane alternative without oxygen, at low temperature (Stevenson et al. 2015). In spite of the low temperature, contrary to what was often said, Titan is not a congealed Earth: the chemical system is not frozen. Titan is an evolving planetary body and so is its exciting chemistry.

Once sedimented on Titan's surface, the aerosols and their complex organic content may follow a chemical evolution of astrobiological interest. Laboratory experiments show that Titan tholins can release many compounds of biological interest, such as amino acids, once in contact with liquid water. This seems even possible with water ice. Those processes could be particularly favorable in zones of Titan's surface where cryovolcanism is occurring. Thus one can envision the possible presence of such compounds on Titan's surface or near subsurface. Long-term chemical evolution is impossible to study in the laboratory: in situ measurements of Titan's surface thus offer a unique opportunity to study by a ground-truth approach some of the many processes which could be involved in prebiotic chemistry, including isotopic and enantiomeric fractionation. The Huygens Descent Imager showed that the reflectance spectra of Titan's

surface was different than any other surface in the solar system (Tomasko et al. 2005). Some of the characteristics of these spectra can be explained by the presence of tholins-like material on the surface. The Cassini Visual Infrared and Mapping Spectrometer (VIMS) has also identified in a global sense the surface properties of Titan with tholins, color properties, as means of categorizing the various surface properties. The source of these inhomogeneities is currently unknown.

However, besides the well-know earth-like life, other forms of living organisms have been speculated to exist in Titan's lakes. McKay and Smith (2005) suggested that some of the methane currently present in Titan's atmosphere could be coming from methanogens, or methane-producing microbes. The microbes would breathe hydrogen rather than oxygen, and eat organic molecules drifting down from the upper atmosphere that they would then metabolize with acetylene instead of glucose, and exhale it in the form of methane instead of carbon dioxide. McKay et al. considered three available substances: acetylene, ethane, as well as tholins, with acetylene, yielding six times as much energy per mole as either ethane or tholins, being the most probable provider. In agreement with this theory, Darrell Strobel found in 2010 larger amounts of molecular hydrogen in the upper atmosphere of Titan as compared to the lower parts, suggesting that the disappearance of hydrogen near Titan's surface could be due to methanogenic life forms if present. Similarly to hydrogen, acetylene was observed to have lower abundance on Titan's surface, again consistent with the hypothesis of organisms consuming hydrocarbons. However, other possible explanations for the decrease of hydrogen and acetylene near the surface exist in possible physical or chemical processes such as a surface catalyst accepting hydrocarbons or hydrogen that remains to be identified or possibly errors in the observations and the models (in particular for the material flow). Stevenson et al. (2015) proposed a model for an "azotosome," a membrane composed of nitrogen, carbon, hydrogen, but no oxygen or phosphorus, which would be capable

of surviving in Titan's liquid methane lakes. But this is still a long way from a new exotic life form that has not yet been detected on Titan (or elsewhere).

Another possible location to look for life on Titan would be in an undersurface liquid water ocean. Indeed, if the models of internal structure are correct, Titan, as Europa, Ganymede, and Callisto, has an internal ocean of liquid water (probably mixed with some ammonia). The presence of an internal ocean is supported by internal models, spin, radar and gravity Cassini measurements (Lorenz et al. 2008b, Iess et al. 2012), and the HASI experiment on Huygens (Béghin et al. 2009), where the extremely low frequency electric signal recorded by HASI was interpreted as a Schumann resonance between the ionosphere and a modestly conducting ocean (since the ice is not conductive) roughly 50 km below the surface. Cassini's measurement of a small but significant asynchronicity in Titan's rotation is most straightforwardly interpreted as a result of decoupling the crust from the deeper interior by a liquid layer. There are now several evidences from the Cassini data confirming the presence of such an internal ocean of crucial astrobiological importance.

Thermal evolution models suggest that Titan may have an ice crust between 50 and 150 km thick, lying atop a liquid water ocean a couple of hundred kilometers deep, with some amount (a few to 30%, most likely ~5%) of ammonia dissolved in it, acting as an antifreeze (Lorenz et al. 2008a). Beneath would lie a layer of high pressure ice (Fig. 7). It has been suggested in a different model by Fortes (2000) that ammonia mixed with liquid water could exist in an undersurface ocean 200 km underneath a water-ice crust. The presence of ammonia, from which Titan's nitrogen atmosphere was presumably derived, distinguishes Titan's thermal evolution from that of Ganymede and Callisto. At the beginning of Titan's history, this hypothetical ocean may have been in direct contact with the atmosphere and with the internal bedrock, offering interesting analogies with the primitive Earth, and the potential implication of hydrothermal

Titan, Fig. 7 Titan's interior and multiple layers. (Credit: NASA/LPGN)

vents in terrestrial prebiotic chemistry. Titan's overall density requires it to have roughly equal proportions of rock and ice. The extent of its differentiation (ice from rock, rock from metal) constrains temperatures in the early Saturnian nebula; Titan was almost certainly warm enough to allow some differentiation – at least partially – into a rocky core with a water/ice envelope but whether an iron or iron–sulfur core formed is not known. Consequently, it cannot be excluded that life may have emerged on or in Titan. In spite of the extreme conditions in this environment, life may have been able to adapt and to persist. Even the possible current oceanic conditions (pH, temperature, pressure, salt concentrations) are not incompatible with life as we know it on Earth. Grasset et al. (2000) suggested that heat transfer between the interior and upper layers on Titan would be essential for sustaining any alien life in the subsurface oceans where biogenic effects in the atmospheric methane and nitrogen might be indicative of microbial life on Titan. However, the detection of a potential biological activity in the current internal Titan's water ocean seems very challenging with current space and ground-based exploration capabilities.

Titan and the Earth

Despite the aforementioned biological possibilities on Titan, there are substantial barriers to the formation and sustainability of life on Titan and hasty analogies with our own planet can prove erroneous. At a vast distance from the Sun, Titan is located at 10 AU at which distance, the temperature and insolation conditions are extremely low. Its atmosphere lacks consequent amounts of oxygen in any form. At the surface, water cannot exist as liquid but only as ice. As a consequence, and although Titan may well harbor a high potential for habitability, it is probably not a good analogue for current or past conditions on Earth.

Similarities with the Early Earth

The direct similarities between Titan and the Earth have been pointed out since the Voyager days: a molecular nitrogen atmosphere like the Earth's, with a surface pressure just 40% larger than that of the Earth. Titan's seasons are longer by a factor of seven than the Earth's (Fig. 8).

Titan, Fig. 8 Titan and the Earth: comparison of their atmosphere composition and processes. (Credit: NASA)

Although Titan is much colder than the Earth, it does present many similarities with our planet, at different levels. Titan's atmosphere is made of the same main constituent, dinitrogen, has a similar complex structure from the troposphere to the ionosphere, and a surface pressure of 1.5 bar, only case of extraterrestrial planetary atmosphere close to the Earth value. Similarities are obvious between the organic chemistry which is very active now on Titan and the prebiotic chemistry which was active on the primitive Earth. In spite of the absence of permanent bodies of liquid water on Titan's surface, both chemistries are similar. Several of the organic processes which are occurring today on Titan imply some of the organic compounds which are considered as key molecules in the terrestrial prebiotic chemistry, such as hydrogen cyanide (HCN), cyanoacetylene (HC_3N), and cyanogen (C_2N_2). In fact, with several percent of methane in dinitrogen, the atmosphere of Titan is one of the most favorable atmospheres for prebiotic synthesis. Until recently, such atmosphere composition was supposed to be far from that of the primitive Earth. However, new modelling of the hydrogen escape

in the primitive atmosphere of the Earth indicates that it may have been much richer in hydrogen and methane than previously thought.

Many analogies can also be made, as already mentioned, between the role of methane on Titan and that of water on the Earth. The greenhouse properties of both constituents and their potential condensation in the conditions of Titan for methane and the Earth for water are part of the similarities. Clouds, precipitation, liquid bodies on the surface, with lakes, seas, and river beds (Fig. 9), are some of the common features. Methane on Titan seems to play the role of water on the Earth, with a complex cycle, which presents several analogies with that of water on Earth (Atreya et al. 2006) but also many differences. It still has to be understood. Indeed on Earth, water is recycled into the interior at subduction zones (sink), and released at mid-ocean ridges and volcanoes (source), which provides the long-term cycle (one to a few hundred million years), see Fig. 2. On Titan, methane is photo-dissociated and forms ethane and other organic products in the atmosphere at similar although shorter timescales (tens of million years) which do not recycle

Titan, Fig. 9 Left: Dendritic structures on the surface of Titan as seen by the DISR instrument on Huygens in a panorama taken from 6.5 km altitude. (Credit: ESA/NASA/JPL/University of Arizona). Right: Cassini

Radar image of Titan's surface at high latitude regions, showing the presence of several large lakes. (Credit: NASA/JPL)

methane. The sink of methane on Titan is relatively well understood, but the source of methane is still very model-dependent. Cassini ISS has detected surface features near the South Pole, having the shape of large lake (Porco et al. 2005). The VIMS instrument has identified the presence of liquid ethane in Ontario Lacus confirming it is liquid (Brown et al. 2008). The Cassini radar has discovered the presence of hundreds of lakes and three large seas in the north polar regions (Stofan et al. 2007), also likely to be of liquid methane and ethane (Fig. 9).

The pictures of Titan's surface provided by the Descent Imager/Spectral Radiometer (DISR) instrument on the Huygens probe show dendritic structures (Tomasko et al. 2005) similar to fluvial networks seen on Earth (Fig. 9). Analogous but larger structures are also observed at coarser resolution on Cassini Orbiter radar images (Lorenz et al. 2008b; Burr et al. 2013 and refs included). These structures are located in relatively young terrains and produced by a recently flowing liquid. Moreover, the Huygens GC-MS (Niemann et al. 2005, 2010) has measured the atmospheric CH_4 abundance from 150 km altitude down to the surface and the data show that above the landing

site, methane reaches the saturation level at an altitude of approximately 8 km, compatible with clouds formation (Fig. 3), although they have not been observed at those latitudes. Such clouds could produce rain which could be the origin of the observed fluvial-like networks. In addition, the gas chromatography measurements after the probe has landed strongly suggest the presence of condensed methane on the landing site (Niemann et al. 2005, 2010).

Many observations of Titan's surface from the Cassini instruments show features evidently derived from diverse geological processes analogous to the terrestrial ones. There are mountains on Titan of several hundred meters high (Radebaugh et al. 2007), sign of the presence of tectonic activity, fluvial and wind-driven features (Fig. 4). A wide variety of Cassini data support the presence of cryovolcanism on Titan. Indeed, at least two regions have been observed to change reflectance on Titan's surface and one of them in RADAR images exhibits lobate "flow" forms, consistent with the morphology of volcanic terrain, supporting the hypothesis of cryovolcanic eruptions (Lopes et al. 2007, 2013). If so, then Titan is presently geologically

active on the surface (Solomonidou et al. 2016) and in its interior. However, on Titan fluid water mobilized and made buoyant by ammonia and other materials replaces terrestrial melted silicates. If Titan is currently active then the questions arise: What is the full extent of current geologic activity? What are the ongoing processes? Are Titan's chemical processes today supporting a prebiotic chemistry similar to that under which life evolved on Earth?

The surface of Titan shows also the presence of sedimentological and meteorological processes, as we see on Earth: there are many large dunes areas (Lorenz et al. 2006, Radebaugh et al. 2008), (Fig. 4) where the terrestrial silica sand is probably replaced, once more, by water ice particles, mixed with the organic material of the aerosols. There are many features that look like terrestrial dry lakebeds, as seen on the pictures of Titan's surface (Fig. 9) taken by DISR (Tomasko et al. 2005). But again on Titan, the terrestrial silica pebbles are replaced by water ice pebbles. Moreover, the lakes and seas (Fig. 9) observed on Titan in the polar regions (Stofan et al. 2007; Mitri et al. 2007) make Titan the only body in the solar system having permanent large liquid bodies on its surface. These very dark features at the high northern latitudes of Titan were finally shown to be liquid-filled (most probably with ethane rich mixtures, Brown et al. 2008) basins—"lakes." The features range in size from less than 10 km² to at least 100,000 km². They are confined to the region poleward of 55°N. To date, some 655 such features have been identified and mapped (Fig. 9).

All of this suggests that Titan maybe even more similar to the primitive Earth than we thought. However, the degree of complexity which can be reached from such an organic chemistry in absence of permanent liquid water bodies on Titan's surface is still unknown, although it could be quite high.

Titan and the Future of Our Planet

Titan is also an analogue, albeit with different working materials, of the future state of the Earth when surface conditions preclude stable equatorial/mid-latitude oceans. If we are to focus

on the Earth and its climate, as well as on its organic chemistry, we need in the future to concentrate on another object in the solar system that sustains an active hydrologic cycle with surface liquids, meteorology, and climate change. The Cassini-Huygens mission has firmly established that Titan is such a body, in which the active working fluid of the hydrologic cycle is methane. The cycle is active but different from the Earth because Titan lacks a surface methane ocean. It possesses, however, methane lakes and seas, fluvial erosion, rounded pebbles, and liquid methane in the soil at the Huygens site.

With Titan, we are observing an active hydrologic cycle subjected to seasonal, annual, and longer term changes, as on the Earth. Moreover, the future increase in the solar luminosity make it almost inevitable that eventually water on the Earth will no longer be trapped in our ocean and troposphere but will escape rapidly in a process we see today for methane on Titan. The late stages of this evolution – an Earth with liquid water in the polar regions, in the crust, but no longer in an ocean – may be echoed by the configuration we see today in Titan's methane hydrologic cycle (Fig. 2).

Future Directions

Lessons from Huygens will be used in the future to go back to Titan and explore in detail and in situ its surface, in many locations. This was already envisaged (Coustenis et al. 2008) with an international mission such as TSSM (Titan/Saturn System Mission). TSSM, jointly studied by NASA and ESA, planned to send a lander to explore one of the Titan's lake, and a Montgolfière to study for several months Titan's atmosphere and surface (Fig. 10). More recently, Dragonfly has been pre-selected as a New Frontier mission to explore Titan in several surface locations with a drone.

Such missions could bring some answers to important astrobiological questions with precise measurements as follows:

- What degree of complexity is achieved by Titan's organic chemistry in the different parts of the geological system?

Titan, Fig. 10 Artist's concepts for future exploration of Titan, either with several drones, like the Dragonfly mission proposed to NASA (left) or by a Montgolfière (hot-air balloon) element of a mission proposed to ESA and NASA. (From L. Matthies, NIAC 2014 Phase I Titan Aerial Daughtercraft Final Report, 2017). (Credit: NASA/STMD)

- Is Titan a habitable world? Does it have an undersurface liquid water ocean or episodic liquid water bodies on the surface?
- Is there currently, has there been or will there be biological activity on Titan?

To answer these questions, new missions dedicated to the detailed exploration of Titan are now needed, such as the Dragonfly mission to be launched, if finally selected, around 2025. Space and ground-based observations along with models and experimental work is needed for us to better understand this complex world. Although life itself may not exist there, our understanding of habitable conditions in the outer solar system and in particular of prebiotic aspects on Titan with its unique organic chemistry remain of great interest in understanding the emergence of life on our own planet and the formation of habitats.

Titania

Therese Encrenaz

LESIA, Observatoire de Paris – Section de Meudon, Meudon, France

Definition

Titania is the fourth of the five biggest satellites of ► [Uranus](#), in terms of increasing distance to Uranus; it is the biggest in terms of mass. It was discovered by Herschel in 1787. It orbits at a distance of 436,300 km (or 17 planetary radii) from Uranus. Its diameter is 1,580 km. The part of the satellite imaged by Voyager 2 in 1981 shows a smooth surface with large canyons and faults. The longest one is Messina Chasmata with an overall length of about 1,500 km. The only large crater, Gertrude, is 326 km in diameter. Titania probably consists of a rocky core and an icy mantle; it orbits inside Uranus' ► [magnetosphere](#).

Titanium Dioxide (TiO₂)

William M. Irvine

Department of Astronomy, University of
Massachusetts, Amherst, MA, USA

Synonyms

[Titania](#); [Titanium dioxide](#)

Definition

Titanium dioxide, TiO₂, is on Earth the naturally occurring oxide of titanium, forming minerals such as rutile, anatase, and brookite. TiO₂ molecules have recently been identified by radio astronomers in the circumstellar envelope of the evolved star VY Canis Majoris (see ► [Molecules in Space](#)). Rutile traveling-wave ► [masers](#) have been used in very sensitive receivers for ► [radio astronomy](#) (e.g., Yngvesson and Kollberg 1965).

History

The principal isotope of titanium is ⁴⁸Ti, but four other stable isotopes are known – ⁴⁶Ti, ⁴⁷Ti, ⁴⁹Ti, and ⁵⁰Ti. Titanium isotopic anomalies (differences from typical solar system values for the relative abundances of Ti isotopes; see Bernatowicz and Zinner 1997) have been found in ► [meteorites](#) and interpreted as possible evidence for the survival of pre-solar material, possibly interstellar dust grains or material from a nearby ► [supernova](#) explosion. The related molecule, titanium monoxide, ► [TiO](#), has long been known to be present in the atmospheres of some cool stars, and it has also recently been detected by radio astronomers in the circumstellar envelope of the evolved star VY Canis Majoris.

Titius-Bode Law

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The Titius-Bode law is the statement that the ► [semimajor axes](#) of planetary ► [orbits](#) in the solar system follow approximately a geometric progression when going from the innermost to the outermost planets. There is no real physical explanation for this law, which stems from observation only and was first introduced by the German astronomers Johann Daniel Titius and Johann Elert Bode around 1770.

The formula for the ► [semimajor axis](#) a reads: $a = (0.4 + 0.3 \times 2^n)$ with $n = -\infty, 0, 1, 2, 3, \dots$ and a in astronomical units.

The formula is fairly correct for the planets that were known when it was proposed, and it correctly predicted the approximate orbit of objects in the asteroid belt (assumed to be a failed planet) and Uranus. However, it failed for Neptune's orbit. Note also that for Mercury $n = -\infty$ which breaks the logics of the law.

TMC-1 Molecular Cloud

Marcelino Agúndez
Instituto de Física Fundamental, CSIC, Madrid,
Spain

Keywords

Molecular cloud · Star formation ·
Cyanopolyne · Molecules in space

Synonyms

[Taurus Molecular Cloud 1](#)

Definition

TMC-1 (Taurus Molecular Cloud 1) is a ridge-shaped dark cloud located in the Taurus Molecular Cloud, a complex of dark clouds located at a distance of only 140 parsec, which makes it one of the nearest sites of star formation. The north-western part of TMC-1 contains an infrared source (IRAS 04381+2540), coincident with a peak in the intensity of NH₃, which suggests that it is more evolved than the south-eastern part, where there is a peak in the emission of cyanopolyynes. The cyanopolyne peak hosts a very rich chemical composition and has been a prominent source for the discovery of new molecules in space.

Overview

The Taurus Molecular Cloud is a dark nebula located in the constellation of Taurus that was discovered in 1852 by J. R. Hind. This nebula is considered to be a stellar nursery, as it contains hundreds of dense molecular cores (Qian et al. 2012), the sites of future star formation, and hundreds of newly formed stars with ages below 2×10^6 year (Kenyon and Hartmann 1995; Luhman et al. 2010). It lies at a distance of 140 parsec (Elias 1978), making it an ideal target to study star formation from the earliest stages (starless and pre-stellar cores) to the later ones (protoplanetary disks and young planetary systems).

Belonging to the Taurus Molecular cloud complex, TMC-1 stands out as a ridge-shaped dark cloud extending $5' \times 15'$ along the southeast to northwest direction. The physical conditions in TMC-1 are those of a cold, dark, dense, and molecular gas. The gas kinetic temperature is very low, around 10 K, and the volume density is a few 10^4 particles (mostly H_2 molecules) per cubic centimeter (Pratap et al. 1997). The densest regions have visual extinctions above 10 magnitudes (Fuente et al. 2019), which implies that the gas is well protected against external visible and ultraviolet radiation from nearby hot stars. Apart from the presence of the infrared source IRAS 04381+2540, located in the north-western part and thought to be a protostellar system (Apai et al. 2005), there is no sign of ongoing star formation activity, which makes TMC-1 an ideal region on which to study the earliest stages of star formation.

TMC-1 has been widely observed in molecular lines. These observations show that the south-eastern region is particularly rich in carbon chain molecules such as C_2S , C_4H , and HC_3N , while in the north-western region, NH_3 is particularly abundant. This fact has led to the identification of two prominent positions in TMC-1, called the cyanopolyne peak, located in the south-eastern part with coordinates $RA(J2000) = 4^h 41^m 41.9^s$ and $Dec(J2000) = +25^\circ 41' 27.0''$, and the ammonia peak, located in the north-western region, close to the IRAS source. The marked chemical differentiation between these two positions has

been an active subject of debate. It has been suggested that the south-eastern part, where the cyanopolyne peak resides, is physically and chemically less evolved than the north-western part, where the NH_3 peak and the infrared source are located (Hirahara et al. 1992). This explanation continues to be the most widely accepted.

The cyanopolyne peak of TMC-1 is not merely a source where carbon chain molecules are abundant, but it is one of the objects of the sky with the largest inventory of molecules detected. This fact has made this source the template on which to confront the results of the majority of chemical models of cold dark clouds (e.g., Agúndez and Wakelam 2013). In recent years, the cyanopolyne peak of TMC-1 has been the scenario of many discoveries of new molecules, with profound implications for our understanding of interstellar chemistry. Families of molecules other than carbon chains have been found to be quite abundant there. Among them, O-bearing complex organic molecules like methyl formate and dimethyl ether (Agúndez et al. 2021), moderately large hydrocarbons like vinyl and allenyl acetylene (Cernicharo et al. 2021a, b), and aromatic cycles such as benzonitrile (McGuire et al. 2018), cyanonaphthalene (McGuire et al. 2021), indene (Cernicharo et al. 2021c), and benzyne (Cernicharo et al. 2021d). The discovery of polycyclic aromatic hydrocarbons (PAHs), either pure or substituted with CN, at the cyanopolyne peak of TMC-1 is the first secure detection of PAHs in space and strongly suggests that PAHs are formed in situ in cold dark clouds through a bottom-up process starting from smaller hydrocarbons.

► Trans-Neptunian Object

Todd, David

William M. Irvine

University of Massachusetts, Amherst, MA, USA

History

David Peck Todd (1855–1939), Professor of Astronomy and Director of the Observatory at Amherst College (Massachusetts, USA) from 1881 to 1920, led 12 solar eclipse expeditions between 1878 and 1914 to all parts of the world; in 1882 the new Lick Observatory chose him to lead the observations of the transit of Venus. He has also been credited with “the first successful astronomical observation from an artificial platform above the Earth’s surface” by sketching Halley’s Comet from a balloon (Sagan and Druyan 1985) and with promoting the Chilean high deserts as excellent astronomical sites (Todd 1908).

He may be considered an early astrobiologist and SETI pioneer from his interest in the possibility of intelligent life on Mars. In 1907 Percival Lowell chose him to lead an expedition to South America to observe a favorable opposition of Mars, with the hope of verifying the “canals” that Lowell and others had reported and ascribed to a technical civilization. This involved dismantling and shipping to Chile Amherst’s new large refracting telescope. Although the expedition’s photographs and drawings left the origin of the Martian surface features ambiguous, Todd was sufficiently intrigued by the results and by Marconi’s recent successful transatlantic radio transmissions to propose as early as 1909 sending signals to and listening for transmissions from Mars. He did persuade the US Army and Navy to observe a period of radio silence during the 1924 opposition of Mars; although unusual

signals were reportedly received, they could not be ascribed to Martians! (Dick 1996).

TTG

Definition

Tonalite-trondhjemite-granodiorite (or TTG suite, a term coined by Jahn et al. 1981) is an association of rocks that compose a large part of Archean continental crust. It is widely accepted that this rock suite formed by melting of hydrous

metabasalts at high pressure, yet the geodynamic setting in which this melting took place is discussed. Two main sources of melt are proposed: (1) basaltic material that was previously underplated beneath thickened crust (e.g., Smithies 2000) and (2) basaltic rocks in subducting oceanic slabs that melted in a hotter Archean mantle (e.g., Martin et al. 2005).

Overview

About 90% of the juvenile continental crust generated between 4.0 and 2.5 Ga belongs to the “TTG suite” (tonalite, trondhjemite, and granodiorite) (Jahn et al. 1981; Moyen and Martin 2012), although in some ► cratons (e.g., Yilgarn Craton, Australia; Champion and Sheraton 1997), high-K monzodioritic and syenogranitic rocks can also be abundant. Most of these rocks are gray orthogneisses (metamorphosed granitic rocks) displaying well-developed foliation and/or banding (Fig. 1a). Typically, the banding consists of an alternation of pale-colored quartz-plagioclase layers with darker biotite and amphibole-rich gray layers (Fig. 1b). From the mineralogical point of view, TTGs are equigranular quartz + plagioclase + biotite-bearing plutonic rocks; K-feldspar, where present, appears in subordinate proportions. The more primitive members of the suites can be hornblende rich. Accessory phases are allanite, epidote, apatite, zircon, sphene, and titanomagnetite (Fig. 2a).

TTGs are silica rich ($\text{SiO}_2 > 64$ wt.%; commonly 70 wt.% or greater) with high Na_2O contents ($3.0 \text{ wt.\%} \leq \text{Na}_2\text{O} \leq 7.0 \text{ wt.\%}$) and correspondingly low $\text{K}_2\text{O}/\text{Na}_2\text{O}$ (< 0.5). They exhibit no K-enrichment during magmatic differentiation (Fig. 2b). They are Al rich and poor in ferromagnesian elements ($\text{Fe}_2\text{O}_3^* + \text{MgO} + \text{MnO} + \text{TiO}_2 \leq 5 \text{ wt.\%}$). Their rare-earth-element (REE) patterns (Fig. 3a) show that they are La-rich and Yb-poor, resulting in strongly fractionated patterns (high La/Yb, up to 150), when compared with the present-day juvenile continental crust that has high Yb contents and poorly fractionated patterns (low La/Yb; Fig. 3b). These features are interpreted as reflecting the presence of garnet and amphibole and

a lack of plagioclase, both as residual or fractionating phases (Martin et al. 2005). The presence of garnet indicates that TTG genesis took place at high pressure (≥ 12 kbars) such that, as pointed out by Champion and Smithies (2003), a high-pressure origin has become implicit in the term “Archean TTG.”

Petrogenetic Models

Consideration of the geochemical characteristics of Archean TTG and the results of experimental high-pressure melts of hydrous basalt have led to

the conclusion that TTG formed via low- to moderate-degree partial melting of hydrated basaltic crust at pressures high enough to stabilize garnet $\pm$ amphibole (i.e., eclogite or garnet amphibolite) (Martin 1987; Rapp and Watson 1995; Moyen and Martin 2012). The lack of mafic endmembers to the TTG suites indicates that partial melting, rather than fractional crystallization, was the dominant process. More recently, Foley et al. (2002) argued that only a garnet-bearing amphibolitic source is able to account for the typically low Nb/Ta and high Zr/Sm ratios

Tonalite-Trondhjemite-Granodiorite, Fig. 3 (a) Chondrite-normalized REE patterns for typical Archean TTG showing their richness in La and their poorness in Yb, which results in high La/Yb ratios, indicating that garnet was stable in the residue of their source. This implies that

their genesis took place at high pressure. (b) Chondrite-normalized REE patterns for modern juvenile continental crust. The relatively high Yb contents point to the absence of residual garnet during their genesis

of TTG. However, Rapp et al. (2003) show that similar ratios can also result from partial melting of hydrous basalt, leaving an eclogitic residue.

In some rare modern subduction environments where a young and hot ► [oceanic crust](#) is subducted, small volumes of TTG-like magmas (Na rich, high La/Yb), called adakites, are generated (Defant and Drummond 1990). The high pressures required for TTG genesis and the compositional similarities with adakites have led to the conclusion that TTG also formed via melting of subducted oceanic slabs (Martin 1986; Martin et al. 2005; Fig. 4). Archean heat production was two to four times greater than today (Brown 1986); consequently, Archean geotherms were significantly greater than typical modern ► [geotherms](#). During the Archean, the “normal” thermal regime was probably quite similar to that observed in modern zones of “hot” subduction, where adakitic magmas are typically produced. Such comparisons clearly support a subducted-slab-melt model for TTG. However, the idea that

adakite is invariably a petrogenetic analogue for all TTGs has recently been challenged. Based on secular changes in TTG compositions, Smithies (2000) and Smithies and Champion (2000) proposed that alternative processes, such as melting of tectonically or magmatically thickened hydrous mafic crust, might be more appropriate for the early Archean TTG. Bédard (2006) has suggested that delaminated hydrous basaltic lower crust sinks into the mantle where it partially melts to produce TTG. More recently, it has been proposed that melting of oceanic plateaus in a subduction environment better accounts for LILE budget in TTG (Martin et al. 2014). On the other hand, Laurent et al. (2020) consider that the composition of TTG plutons of South Africa rather reflects the combined accumulation of plagioclase phenocrysts and loss of interstitial liquid that erupted as silicic volcanic rocks. They conclude that the entire compositional diversity of TTGs could derive from the upper crustal differentiation of a single, tonalitic magma formed by basalt melting.

Tonalite-Trondhjemite-Granodiorite, Fig. 4 Pressure-temperature (P-T) diagram and schematic cross-section of a subduction zone illustrating a possible interpretation of the formation of TTG. In the early Archean ($t > 3.5$ Ga), the geothermal gradient along the Benioff plane was very high; subducted slab melted at shallow depth with plagioclase as residual phase. Because of the small thickness and low temperature of the wedge, mantle-melt interactions were limited or absent (red arrow and inset (a)). At the end of Archean ($3.0 < t < 2.5$ Ga), Earth was cooler and the geothermal gradient along Benioff plane was lower;

slab melting occurred at greater depth without residual plagioclase. The overlying mantle wedge was thick and hot, and interactions may have occurred between slab melts and the mantle (orange arrow and inset (b)). After 2.5 Ga, Earth had cooled further and the geothermal gradient along the Benioff plane was still lower (blue arrow and inset (c)) such that slab dehydration generally occurred before its melting could begin. The expelled volatiles (mainly water) ascended through the mantle wedge, thus lowering its solidus temperature, which induced its melting

The P-T diagram shows the solidus of tholeiite with 5% water as well as main dehydration reactions of oceanic lithosphere. H is hornblende, A is anthophyllite, C is chlorite, Ta is talc, Tr is tremolite, and Z is zoisite. G and P outline stability fields of garnet and plagioclase, respectively. The gray field is P-T domain where slab melts can coexist with hornblende- and garnet-bearing residue. OC is oceanic crust; CC is continental crust; and ms is solidus of hydrated mantle. Areas in red indicate magma; light blue indicates dehydration volatiles

Change in TTG Composition Through Time

Recently, Smithies (2000), Smithies and Champion (2000), and Martin and Moyen (2002) showed that the chemical composition of TTGs changed through the Archean. Throughout that eon, the most remarkable change was a decrease in average SiO_2 and an increase in average MgO content. According to Martin and Moyen (2002), the Mg# of the more primitive TTG magmas increased from maximum values of 0.45 at 4.0 Ga to 0.65 at 2.5 Ga. These authors also pointed out that over the same time interval, the

maximum concentrations of Ni increased from ~30 to ~70 ppm, Cr from ~50 to ~200 ppm, Sr from ~550 to ~1,200 ppm, and (Na₂O + CaO) from 9 to 11 wt.%. They interpret the high Mg# and the high Ni, Cr, and Sr contents in TTG parental magmas as due to the deep melting of the subducted basalt, which interacts with a thick slice of the mantle wedge peridotite. Recently, Smithies et al. (2019) considered that, during the Archaean, basalt melting depth never exceeds 50 km.

However, considering elements other than Sr, Ni, Cr, and Mg, the close similarities in the compositional range for TTG are independent of age and suggest a common petrogenetic relationship that is also age independent. In the younger TTG, the high Mg# and high Ni are thought to arise as magma derived by great-depth melting of subducting oceanic crust, which interacts with peridotite of the mantle wedge (Smithies et al. 2019). The lower Mg# and low Ni, Cr, and Sr contents in the older TTG indicate the lower efficiency of such interaction, perhaps because melting took place at shallower depth, under a thinner (or even with no) mantle wedge.

Definition

Toutatis is a near-Earth asteroid of the Apollo class, with an orbit that crosses Earth's orbit so that it is classified as a potentially hazardous asteroid. With its 1:4 resonance with Earth's orbit, it has been observed carefully since 1992

with astronomical telescopes and radar during its close flybys every 4 years. In 2012 it passed by the Earth within just 18 lunar distances, which will be the closest flyby for more than a century. During this flyby the Chinese spacecraft Chang'e 2 observed Toutatis from a distance of less than 1 km and could see details down to a size of a couple of meters.

Toutatis is a stony type asteroid (S (IV)) with a density of about 2.5 g/cm³; it has an elongated shape (4.75 × 1.95 km) and seems to consist primarily of two large pieces, leading to speculation that the asteroid has a rubble-pile structure resulting from a large impact. Toutatis has a slow tumbling rotation with just one rotation per 5.4 days on the long axis and a long-axis precession of 7.4 days.

History

Astronomer Christian Pollas discovered Toutatis on January 4, 1989.

Trace Elements

Nicholas Arndt
ISterre, University Grenoble Alpes, Grenoble, France

Definition

On Earth a trace element is an element present in low concentrations in rocks, in waters, or in biological materials. A concentration of 100 parts per million (ppm) is commonly accepted as an upper limit. In geochemistry, trace elements are distinguished from major elements. The importance of trace elements is their lack of mutual interaction, which is the basis of Henry’s law of dilute solution. Major elements are the essential constituents of the crystal framework of minerals and rocks; trace elements substitute for or replace major elements. The concentrations of trace elements in rocks and minerals vary from several thousands of parts per million (e.g., strontium or nickel) to a few parts per billion for elements like platinum.

► [Rare Earth elements](#) are trace elements belonging to the family of lanthanides. In biology, a trace element is defined as an element that is present in low concentrations but is essential for the growth, development, and physiology of an organism. Trace elements are useful for monitoring the evolution of the core, mantle, and crust of the Earth and other planets; the appearance and evolution of life through geological time, as well as climate change in the past and at present; and the impact of industry on the environment.

Definition

Trace metals are metallic elements on the periodic table that are found in low concentrations in both aqueous environments (seawater, freshwater, mine waters) and geologic samples (minerals, rocks, and mine tailings). In aqueous environments, trace metals include any metal element present at concentrations between 10^{-15} mol/L (1 fM) and 10^{-5} mol/L (10 μ M). In geological samples, trace metals are present in abundances of <0.1% by weight and typically quantified in either ppm (mg/kg) or ppb (μ g/kg). With regard to trace metals in astrobiology and geobiology, there is an increased focus on transition metals in columns 3–12 of the periodic table.

Overview

Trace metals are ubiquitous components of aqueous environments, geological samples, and

biological processes. In biological systems, trace metals play critical roles as reaction centers and structural components in metalloenzymes or can even be used as terminal electron acceptors in redox-driven metabolisms such as manganese reduction. Within metalloenzymes, trace metals act either as reaction centers or as a structural component that enhances the integrity of enzymes. This is especially true of the first-row transition metals (V, Mn, Fe, Co, Ni, Cu, and Zn) as well as Mo. While essential for life at low concentrations, at elevated concentrations many trace metals (Fe, Cu, Zn, etc.) prove toxic. Thus, trace metals offer the potential to trace biological processes in modern and ancient environments and from an astrobiological perspective may be useful as a paleoenvironmental or biotic tracer.

Trace Metals in Seawater

In aqueous environments, such as seawater, trace metals tend to display one of the four profile types: (i) conservative, (ii) nutrient-like, (iii) particle-scavenged, or (iv) a hybrid distribution (Bruland et al. 2014). Trace metals with conservative profiles (e.g., Mo, W, Re) are those that have high concentrations relative to the efficiency of their sinks, and they tend to display little variation in concentration. In nutrient-like profiles, trace metals (e.g., Zn, Cd, Ag) are heavily depleted in the shallow surface water because of incorporation by phytoplankton communities through either surface adsorption or assimilation. Both processes are a function of microbial surface reactivity and microbial metal binding. These trace metals are then replenished at depth, as cellular biomass decays, and eventually return to the photic zone via upwelling. Conversely, particle-scavenged trace metals (e.g., Co) exhibit peak concentrations in the ocean's surface and become depleted at depth. This may be due to settling following their adsorption onto reactive particles or biological surfaces or through their incorporation into authigenic marine precipitates (i.e., chemical sediments formed in marine systems). Ultimately, this results in the export of trace metals to seafloor sediments. Certain elements may be defined by a hybrid distribution, a notable example being Fe (Bruland et al. 2014). Elements

that display a hybrid distribution are dependent on the geographical location and basin characteristics, which ultimately dictate whether they display nutrient-like or particle-scavenged features. Notably, the profile type of a given trace metal can be dependent on the prevalent biological and redox conditions in the oceans and can change on geological timescales.

In modern oceans, trace metals are strongly bound by microbial ligands, in some cases exceeding 97% of their total concentration. Chelation by microbial ligands is especially prevalent for Fe, Zn, Ni, Co, Cd, and Cu (Vraspir and Butler 2009; Bruland et al. 2014). Perhaps the best-known examples are the Fe-specific ► [ligands](#), siderophores, which act to keep insoluble Fe(III) in solution, thereby increasing Fe bioavailability for planktonic microbial species. Conversely, other ligands may act to decrease the free concentrations of trace metals, such as Cu, keeping them below toxic levels for microbial communities (Bruland et al. 2014). Today, Fe is a co-limiting nutrient over large areas of the oceans, depressing nitrogen fixation and primary productivity (e.g., Falkowski et al. 1998; Mills et al. 2004). Yet, despite the potential for Fe co-limitation in the modern ocean, on geological timescales, phosphorous is considered to be the ultimate limiting nutrient (Tyrrell 1999).

Trace Metals as Drivers of Ecosystem Change

Changes in the bioavailability of these trace elements have long been recognized to have the potential to drive biological evolution or control ecosystem structure over geological time (e.g., Frausto da Silva and Williams 2001). It has been suggested that the timing of the proliferation of specific metalloenzymes should broadly track changes in the environmental availability of the requisite trace metals (Dupont et al. 2010). Further, it has been debated if environmental trace metal availability limited the size and scope of the biosphere for much of Earth's early history (e.g., Anbar and Knoll 2002). For example, methanogens have a high requirement for Ni, due to its incorporation into enzymes needed to carry out methanogenesis (Ragsdale and Kumar 1996). It follows that methanogens would be

sensitive to environmental fluctuations in Ni availability (see discussion below).

Sedimentary Trace Metal Archives

Trace metal concentrations in the oceans in deep time, and by extension first-order trends in their bioavailability, are primarily unlocked by examining trace metal abundances in marine chemical sediments. These archives include black shales (e.g., Scott et al. 2008, 2013; Chi Fru et al. 2016), banded iron formations (e.g., Konhauser et al. 2009, 2011; Robbins et al. 2013), sedimentary to early diagenetic pyrite (e.g., Large et al. 2014; Mukherjee et al. 2018), and carbonates (Liu et al. 2016). Reconstructions of trace metal inventories of these records have been variously related to the ► [oxygenation of Earth's atmosphere](#) (Mo, V, Zn), the marginalization of methanogens (Ni), the onset of aerobic oxidation of terrestrial minerals (Cr), and the role that intrinsic biological processes may play in the evolution of complex life (Zn, Cu). Additional trace metal compilations produced temporal records for V (Sahoo et al. 2012), U (Partin et al. 2013a, b), Co (Swanner et al. 2014), and Re (Sheen et al. 2018). While these records are variably susceptible to overprinting during ► [diagenesis](#) and metamorphism, it is telling that many of the temporal trends are reproducible across multiple chemical sedimentary records, suggesting that these sedimentary archives are tracking first-order trends in global trace metal concentrations in seawater.

Basic Methodology

Today, the most common methods for measuring trace metal concentrations involve the use of inductively coupled plasma mass spectrometry (ICP-MS) or optical emission spectroscopy (ICP-OES). These methodologies can be used to directly analyze aqueous samples and, via laser ablation, geological samples. Additionally, both anodic and cathodic voltammetric stripping have been used in measurements of shipborne seawater samples and have proven critical in assessing the degree of organic ligand complexation of trace

metals such as Fe, Zn, Cu, and Cd (Bruland et al. 2014).

Aqueous Samples

Generally speaking, for aqueous samples including seawater and freshwater, a sample is collected and then filtered and acidified prior to analysis. Filter size is generally in the range of 0.22 μm such that microbial, particulate, and colloidal material is removed and the dissolved concentration of trace metals is measured; although, ultrafiltration is common and provides a true dissolved concentration. Following collection, samples may be diluted in a weak acid and introduced into an ICP-OES or ICP-MS or measured directly depending on instrument sensitivity and initial metal concentration. Analyses are generally calibrated against internal matrix-matched standards prepared with certified, commercial standards.

Geological Samples

Geological samples (e.g., banded iron formations, black shales, carbonates, pyrite) may be completely digested using various concentrated acids (such as a combined HNO_3 -HCl-HF attack). This involves several steps of acid addition, heating the sample, and evaporating the sample to a residue. The residue is then dissolved into a dilute acid matrix, typically 1–2% HNO_3 , and analyzed by ICP-MS. Alternatively, samples may be subjected to a series of sequential extractions designed to leach the authigenic and typically more reactive phases. Analyses are typically calibrated against internal standards and compared to well-characterized geological standards. Alternatively, trace metals may be measured by coupled laser ablation ICP-MS. In LA-ICP-MS analysis, a geological sample (thin section, small rock or mineral) is ablated in an airtight chamber with a laser, and the liberated fine particles are then carried to the ICP-MS by an inert gas line. Similar to solution analyses, LA-ICP-MS measurements are calibrated against well-known geological standards. Stable isotope measurements of trace metals are becoming commonplace by multi-collector ICP-MS (MC-ICP-MS), which often require additional sample processing and purification.

Key Research Findings

While the fact that >97% of certain trace metals are organically complexed in seawater is a profound observation in of itself (Vraspir and Butler 2009; Bruland et al. 2014), some of the most powerful inferences regarding trace element chemistry and their relation to Earth systems evolution have been garnered from the geological record. For instance, the enrichments of several transition metals in black shales, including Mo, V, Cr, U, and Re (Scott et al. 2008; Sahoo et al. 2012; Partin et al. 2013b; Reinhard et al. 2013; Sheen et al. 2018), are known to track the two-stage oxygenation of the ocean-atmosphere system (see Lyons et al. 2014 for a review).

A late-Archean secular decline in Ni/Fe ratios in banded iron formations indicates a decrease in Ni bioavailability (Konhauser et al. 2009, 2015) that is critical for methanogens (Ragsdale and Kumar 1996). This secular decline is the result of decreasing komatiite weathering and may have led to the marginalization of ancient methanogens, allowing for oxygenic cyanobacteria to expand into previously occupied environmental niches. These events, in turn, led to the first permanent rise in atmospheric oxygen ~2.48–2.3 Ga, a period known as the Great Oxidation Event (GOE) (e.g., Konhauser et al. 2011).

While Mo, V, U, Cr, Re, and Ni show stark temporal trends that track the rise and fall of oxygen, several trace metals show records that are considerably more static in both banded iron formations and black shales. Static records for trace metals, such as Zn and Cu (Robbins et al. 2013; Scott et al. 2013; Chi Fru et al. 2016), hint at the possibility of pervasive microbial ligand complexation in deep time, which would have stabilized trace metal concentrations against changes in bulk ocean chemistry or atmospheric conditions. These static records stand in stark contrast to the assertion that evolving trace metal abundances should be trackable by the proliferation of corresponding trace metal complexes in biological systems (e.g., Dupont et al. 2010). For example, despite geological evidence that points toward an attenuated marine reservoir for Mo in the Archean to Proterozoic (Anbar and Knoll

2002; Scott et al. 2008), isotopic evidence points to an Archean appearance of Mo nitrogenase (Stüeken et al. 2015). This questions the idea that an organism's elemental stoichiometry always reflects the fundamental chemistry of the environments in which they evolved.

Future Directions

Transition metals and their isotopes are increasingly measured in both modern and ancient settings. The advent of MC-ICP-MS has led to a rapid proliferation of trace and transition metal isotope data. Studies that utilize this new avenue of data collection are primed to explore the response of the ancient biosphere to changes in environmental conditions or shifts in community structure. For instance, recent examinations of zinc isotopes have shown shifts in their signature that coincide with the rise of eukaryotes to dominance at ~800 Ma (Isson et al. 2018) and may indicate the recovery of biosphere primary productivity or changes in zinc cycling following the Cryogenian glaciations at ~635 Ma (Kunzmann et al. 2013; John et al. 2017). Copper isotopes measured in black shales (Chi Fru et al. 2016) show a distinct shift around the GOE and are attributed to changes in oxidative weathering and a decline in banded iron formations, whereas changes in Mo isotope ratios through the Paleoproterozoic point to major fluctuations in redox balance in the oceans (Asael et al. 2018). Studies such as these highlight the utility of non-traditional stable isotopes of trace metals in extracting information about changes in ancient environmental conditions and offer a clear avenue for future studies that can be focused on shifts recorded in a given basin or over geological time.

Traces of Life in Basaltic Crust

Magnus Ivarsson
Department of Paleobiology, Swedish Museum of Natural History, Stockholm, Sweden

Keywords

Deep biosphere · Igneous crust · Fossilized microorganisms

Definition

Traces of life in basaltic crust refer to signs of past life, including fossilized microorganisms and ichnofossils that reflect microbial activity, in mafic rock. The organisms were once engaged in an endolithic, that is, rock-dwelling lifestyle colonizing open pore space, such as fractures or vesicles, and preserved in situ upon their death. A majority of the fossil remains have been found in subseafloor basalts or ancient oceanic crust (Fig. 1), and only rarely in continental settings. Body fossils are found throughout the basaltic

Traces of Life in Basaltic Crust, Fig. 1 Image showing the oceanic crust and endolithic habitat

formations, while ichnofossils are almost exclusively found in volcanic glass of pillow lavas.

History

Studies date back to Ross and Fisher (1986), who reported etched grooves in glass shards from a Miocene tephra (an air bourn volcanic deposit). They compared the etch marks with fungal borings in carbonate grains and suggested that fungi

were responsible for the production of the ichnofossils. In the early and mid-1990s, several observations were made of granular and tubular microstructures in volcanic glass from drilled and dredged samples from the ocean floor (Thorseth et al. 1992, 2003). A prokaryotic affinity was assigned to these findings even though a fungal origin of tubular ichnofossils has also been inferred (Staudigel et al. 2008). In the 2000s, fossilized microorganisms were described from various deep seafloor settings, (Schumann

et al. 2004; Ivarsson et al. 2008a, b; Peckmann et al. 2008) and during the last decade a more comprehensive fossil record of the deep basaltic crust has been established (Ivarsson et al. 2012, 2013, 2020; Bengtson et al. 2014, 2017). The concept of a diverse deep biota of prokaryotes and eukaryotes as well as symbiotic-like relationships between the two is now emerging based on the fossil evidence and microbiological studies. This is a significant change of view, considering that the deep igneous oceanic crust was considered barren of life prior to the 1990s.

Overview

Traces of life in basaltic crust comprise three different types: (1) body fossils, (2) ichnofossils, and (3) chemofossils (Ivarsson et al. 2020). The first category constitutes fossil remains of mineralized or encrusted microbial cells. A majority of the body fossils consist of purported fungal fossils such as hyphae, yeast-like structures, sporophores, and resting structures. The fungal interpretation of the fossils has been based on specific fungal morphologies such as septa, anastomoses, reproduction structures, or the presence of chitin (Ivarsson et al. 2012, 2020). The fossils are usually mineralized by montmorillonite clays or occasionally iron oxides. Encrusted and mineralized cells of inferred prokaryotic origin have also been reported, and usually interpreted as the remains of iron- or manganese-oxidizing prokaryotes (Thorseth et al. 2003). Laminated micro-stromatolitic structures are believed to be the products of cyclic biofilm formation of iron- and manganese-oxidizing bacteria, even though an abiogenic influence cannot entirely be ruled out. Complex, branching microstromatolites are referred to as *Frutexit* (Bengtson et al. 2014).

The second category is ichnofossils, described in the literature as traces of microbial activity in volcanic glass, and occasionally olivine. They constitute etch marks with conspicuous granular and tubular morphologies (Staudigel et al. 2008; McLoughlin et al. 2009, 2010). The granular type consists of micrometer-sized, near-

spherical voids etched into the fresh glass, and subsequently filled with authigenic minerals like clays and Fe oxides/hydroxides. They commonly occur in irregularly distributed clusters. The tubular type consists of smoothly curved, sometimes segmented tubes with branched or spiraling morphologies. They usually occur in assemblages and are commonly associated with the granular morphology. The two morphologies are formalized in the ichnogenera: *Granulohyalichnus* and *Tubulohyalichnus* (McLoughlin et al. 2009), which are further subdivided into five ichnospecies on the basis of morphological variations. Fisk and McLoughlin (2013) further produced a comprehensive photographic atlas of ichnofossils and other structures in volcanic glass. Recently, the biogenicity of the oldest Archean trace fossils has been questioned and debated (Grosch and McLoughlin 2014).

The third category is chemofossils: the remains of chemical signatures specific for life, such as biomarkers or isotopic signatures. The preservation of chemofossils is rare in basaltic crust, but $\delta^{34}\text{S}$ values in pyrite corresponding to microbial sulfur cycling and $\delta^{13}\text{C}$ values in organic material as well as vein carbonates consistent with methane cycling (Lever et al. 2013) have been reported. Fluorescent staining has also been used to detect nucleic acids and DNA associated with ichno- and body-fossils, as well as specific stains that detected chitin in fungal fossils (Ivarsson et al. 2008b, 2012).

All traces of life in basaltic crust represent endolithic life forms (including chasmo-, crypto-, and euendoliths) and are thus found at the interface between host rock and pore space, open, or filled with secondary minerals. Body fossils are the remains of microorganisms that used the vein or fracture walls as substrate for growth and therefore have a perpendicular growth direction with respect to the host rock. Ichnofossils in volcanic glass occur conversely to that: still perpendicular to the surface of the glass, but stretching inwards forming negative cavities.

A majority of the fossil remains are found in deep drill cores and are thus considered to represent the deep biosphere. The deep biosphere represents one-tenth to one-third of all living biomass

today, but it has been put forward that prior to the colonization of land in the Ordovician most of Earth's biomass (~80%) was to be found in the deep biosphere (McMahon and Parnell 2018). This suggests that deep environments have played a crucial role in life's history and that fossils of the deep biosphere hold a key to our understanding of early evolution of both prokaryotes and eukaryotes. The fossil record of basaltic crust range from the present back to Devonian ages in ophiolites. Rare reports of much older deep biosphere fossils suggest life to be present in igneous oceanic crust already at 2.4 Ga (Bengtson et al. 2017), and sulfur isotope signatures in pyrite indicate life in subseafloor basalt already at 3.45 Ga (Aoyama and Ueno 2018).

In an astrobiological context, traces of life in mafic crust (e.g., Fisk and Giovannoni 1999) are important because all terrestrial planets in the solar system, except Earth, consist almost exclusively of basalts. Thus, traces of life in basalts have been targeted for upcoming missions designated for the search for signs of life on other planets.

Trans-Neptunian Object

Therese Encrenaz
LESIA, Observatoire de Paris, PSL Université,
CNRS, Sorbonne Université, Université de Paris,
Meudon, France

Synonyms

[Kuiper belt object](#); [TNO](#)

Definition

The name “trans-Neptunian object” (TNO) has been given to the small solar-system bodies that constitute the Kuiper belt, beyond the orbit of Neptune. The existence of this population was first proposed by Kenneth Edgeworth and Gerard Kuiper on the basis of dynamical considerations. Over 4100 trans-Neptunian objects are known by the end of 2021. The first discovery of a TNO was made in 1992 by David Jewitt and Jane Luu. Trans-neptunian objects are classified in different categories: the “classical” objects, at 42–47 AU from the Sun, have a low inclination and a low ► [eccentricity](#); the “plutinos” are in resonance with Pluto and have the same semimajor axis as Pluto; and the “scattered” objects are more distant and have larger eccentricities.

Synonyms

[RNA synthesis](#)

Definition

Transcription is the synthesis of an ► [RNA](#) chain by copying a complementary ► [DNA](#) strand of a particular ► [gene](#) (or cluster of genes in bacterial operons). Both in prokaryotic and eukaryotic cells, a DNA template is required for transcription as well as the four ribonucleoside triphosphates (ATP, GTP, CTP, and UTP) acting as substrates and the enzyme RNA polymerase. As a result, a molecule of RNA (mRNA, tRNA, or rRNA) is produced. The initiation of transcription usually requires the presence of an upstream promoter sequence – i.e., a specific sequence to which RNA polymerase binds tightly and that indicates where to start the transcription and which strand of DNA to transcribe. Some RNA viruses (e.g., human immunodeficiency virus, HIV) make a DNA copy of their genome, i.e., synthesize a DNA molecule using RNA as template in a process called reverse transcription (these viruses are known as retrovirus).

Transduction

Juli Peretó

Institut Cavanilles de Biodiversitat i Biologia Evolutiva, Universitat de València, València, Spain

Definition

1. Genetics sense. Transduction is a ► [virus](#)-mediated transfer of DNA from one cell to another. Although transduction was first observed in bacteriophages and bacteria, it has also been observed in retroviruses and eukaryotic cells.
2. Bioenergetics sense. Transduction refers to any of the diverse mechanisms of conversion between different types of energy, for example, from chemical to mechanical (cell motility), from electromagnetic to chemical (► [Photosynthesis](#)), or from chemical to osmotic (ion pumps).
3. Cell regulation sense. Transduction refers to any of the diverse processes of conversion of information based on the use of chemical signals, for example, the hormone-mediated generation of a second messenger and its effects on metabolic flux regulation.

Center for Chemical Evolution, Georgia Institute of Technology, Atlanta, GA, USA

Definition

In biochemistry, a transferase is an ► [enzyme](#) or ► [ribozyme](#) that catalyzes the transfer of a chemical group (e.g., acetyl, methyl, amino, or phosphate group) from one molecule, the donor, to another, the acceptor. There are more than 450 known protein enzyme classes that catalyze the transfer of various chemical groups from one compound to another. For example, transaminases catalyze the transfer of an amino group from an amino acid to an α -keto acid.

Transformation

Juli Peretó

Institut Cavanilles de Biodiversitat i Biologia

Evolutiva, Universitat de València, València, Spain

Definition

Transformation is a process in which a cell takes up and functionally integrates exogenous ► [DNA](#). There are many examples of natural transformation between bacteria, virus and bacteria, bacteria and plants, or virus and eukaryotic cells. Genetic engineering techniques are artificial adaptations of cases of natural transforming systems.

History

The process of transformation was initially described by Fred Griffith (1877–1941) in 1928 (Griffith 1928). The experiments on the transformation of pneumococcal bacteria, published in 1944 by T. Oswald Avery (1877–1955), Colin MacLeod (1909–1972), and Maclyn McCarty (1911–2005), established that the genetic information is chemically written in DNA (Avery et al. 1944).

Transit

David W. Latham¹ and Nader Haghighipour²
¹Harvard-Smithsonian Center for Astrophysics, Cambridge, MA, USA
²Institute for Astronomy, University of Hawaii-Manoa, Honolulu, Hawaii, HI, USA

Definition

In astronomy, a transit is the occurrence, as seen by an external observer, of a partial ► [eclipse](#) of a body (star, planet) by another body (star, planet) orbiting the first one. The transit refers to the entire duration of the phenomenon. Historically, the observations of the transit of Venus in front of the Sun as seen from Earth, and especially the ones in 1761 and 1769, have been the occasion

to measure the Sun–Earth distance with a fair accuracy. The last transit of Venus across the Sun was in 2012.

The transit phenomenon presents a powerful method for detecting extrasolar planets. Thanks to the *Kepler* space telescope and now the TESS and CHEOPS satellites and many ground-based instruments (e.g., HATNet, MEarth, SPECULOOS), this method has been able to detect close to 2400 extrasolar planets. The transit of an extrasolar planet in front of its host star is also used to determine several of the planet's parameters such as its radius, period, and eccentricity. It is also the most promising technique for characterizing exoplanets atmosphere.

Exoplanets · Spectroscopic orbit · Transit

Definition

Transiting planets are those that orbit stars beyond the solar system and are observed to ► [transit](#) across the disk of their host star.

History

The 1995 discovery of a Jupiter-mass planet orbiting the solar-type star 51 Pegasi with a remarkably short period of 4.2 days opened the eyes of astronomers to a promising new way to detect and study exoplanets. If planets in such tight orbits were common, then the chances that some of them would transit their host stars could be as high as one in ten, because the probability that a planet's orbital plane is properly aligned to cross the disk of its star is roughly R_S/a , where R_S is the radius of the star and a is the distance from the planet to the star. By 1999, enough close-in planets had been detected by the ► [radial velocity](#) method that the odds for one to be transiting its host star were very good. As often happens in science, the actual discovery was made almost simultaneously by two different teams, and the two papers announcing that a giant planet transited HD 209458 were published back to back in the *Astrophysical Journal Letters* in 2000.

Several teams realized that an effective way to discover transiting planets would be to monitor the light of a large number of stars, looking for the slight dimming due to a planet passing in front of the star and blocking some of its light. For a planet the size of Jupiter passing in front of a star like the Sun, the dimming would be about 1% and would last just a few hours. If close-in ► [giant planets](#) were as common as 1 in 100 and the chances were that 1 in 10 would transit, then the yield should be about one transiting planet per 1000 stars. Projects to monitor the light of many thousands of stars looking for microlensing events had a head start, and the OGLE team identified several dozen candidates transiting planets. Eventually, a handful of these candidates were confirmed as planets based on spectroscopic orbits. However, the OGLE candidates were all quite faint and difficult to confirm and characterize. The job of discovering brighter candidates fell to wide-angle surveys that covered

much larger areas of the sky using ► [CCD](#) cameras mounted on telephoto lenses, typically with apertures of 100 mm. The Trans-Atlantic Exoplanet Survey (► [TrES](#)) was the first of the wide-angle photometric surveys to confirm a transiting planet, followed soon by the Hungarian-made Automated Telescope Network (► [HATNet](#)), the Wide-Angle Search for Planets (► [WASP](#)), and the XO Project.

In the meantime, radial velocity surveys were undertaken specifically aimed at finding short-period planets that might then be shown to transit. Two of the planets found this way, ► [HD 189733b](#) and HD 149026b, proved to be among the best targets for follow-up studies of giant planets, primarily because their host stars are nearby and bright, much brighter than the typical transiting systems found by even the wide-angle surveys.

The photometric precision that can be achieved from the ground with small telescopes is limited by the Earth's atmosphere, both by rapid variations due to scintillation and by slower variations in atmospheric extinction (transmission) and seeing (image quality). This motivated the development of photometric space missions to search for transiting planets, first the French-led CoRoT mission, launched in December 2006, and then NASA's ► [Kepler mission](#), launched in March 2009. CoRoT was scoped to have the ability to detect planets as small as super-Earths, and its discovery of CoRoT-7b, a rocky planet in a 0.85-day orbit around an 11th magnitude K dwarf, is the most important planet discovered by CoRoT so far. The design of *Kepler* was much more ambitious, with the goal of detecting true Earth twins, namely Earth-sized planets in 1-year orbits around stars like the Sun. This led to a strategy of monitoring 150,000 solar-type stars in a single field of 100 square degrees in Cygnus and Lyra for nearly 4 years. During the course of its primary mission, *Kepler* identified more than 900 transiting planets (and close to 3000 planetary candidates) with most of them smaller than Neptune. For both CoRoT and *Kepler*, the challenge is now to sort out which candidates are actually transiting planets and which ones are systems of stars that show light curves that mimic transiting planets. The CoRoT and *Kepler* (and its follow-up, K2)

satellites are no longer functioning. However, other space missions are now on sky, detecting and characterizing new planets: TESS (a NASA mission, which began observations in 2018) and CHEOPS (a Swiss-led mission, which began observations in 2020). Both are designed to observe planetary transits around bright stars to detect new planets and to improve the radius estimates. These planets can then be observed from the ground to obtain radial velocities.

In recent years, there has been a growing interest in searches for planets orbiting M dwarfs. This is because it may be easier to discover and characterize rocky planets orbiting M dwarfs in the ► [Habitable Zone](#), where water might be liquid on the surface and life as we know it could potentially develop. M dwarfs offer two main advantages compared to the Sun. They are much cooler, so the Habitable Zone is much closer in, corresponding to periods as short as a few weeks or even days. The tighter orbits and shorter periods in the Habitable Zone imply that it is more likely for a habitable planet's orbit to be aligned so that transits are observed. In addition, the reflex motion of the host star is much larger, both because the mass of an M dwarf is smaller than that of the Sun and because the orbital period in the Habitable Zone is shorter. This has led to photometric surveys looking for planets transiting M dwarfs. The first major initiative is the MEarth project, which has discovered several small planets, like GJ 1214b and more recently LHS-1140b, a 1.7 Earth radius planet in the Habitable Zone of its star (Dittmann et al. 2017). Later, SPECULOOS, another photometric survey joined the game. Its prototype, TRAPPIST, allowed to detect the amazing TRAPPIST-1 system (e.g., Gillon et al. 2017).

Overview

Transiting planets are important because they have enabled studies of whole new areas in the astrophysics of exoplanets, such as the structure of planetary interiors, the temperatures and compositions of their atmospheres, and the formation and evolution of planetary systems.

If a ► [spectroscopic orbit](#) is available for the star hosting a transiting planet, then both the radius and the mass of the planet can be determined. Combining the mass and radius yields the bulk density of the planet, which can be compared with theoretical models of planetary interiors to constrain the composition and structure of the planet. This is illustrated by Fig. 1, which shows a mass versus radius diagram for the planets in the Solar System together with a subset of the transiting planets known in 2007. The lines in Fig. 1 illustrate the masses and radii predicted by models for planets with different compositions, ranging from gas giants dominated by hydrogen and helium at the large end to water worlds and rocky planets at the small end.

Transiting Planets, Fig. 1 The mass versus radius diagram for the planets in the Solar System and a subset of the transiting planets known in 2007. The lines illustrate the masses and radii predicted by models of planets with different compositions. The horizontal axes are plotted in Earth masses (bottom) and Jupiter masses (top); the vertical axes are plotted in km (left) and Jupiter radii (right)

A spectacular application for transiting planets has been the detection and even spectroscopy of planetary atmospheres during transits and secondary eclipses. Spectral features due to molecules such as water, methane, and carbon dioxide have been identified in the atmospheres of the transiting planets plotted as filled diamonds on Fig. 1. In the case of HD 189733b, the thermal emission from the planet has been tracked for more than half an orbit, as the view marched around from the night-side to the dayside. This allowed a map of the temperature of the atmosphere to be constructed as a function of longitude on the planet.

By tracking the radial velocities during transit events, it has been possible to deduce the amount of misalignment between the spin axis of the host star and the normal of the orbital plane, using the so-called ► [Rossiter-McLaughlin effect](#) (see also Fig. 3). In some cases, the plane of the orbit is closely aligned with the star's equator, but the misalignment is often observed to be large and even retrograde. This leads naturally to the interpretation that at least two mechanisms have been responsible for the migration of giant planets from the outer regions of the protoplanetary disks where they formed to the inner regions where they are now observed: Gradual migration in a disk versus violent gravitational scattering followed by tidal dissipation of the orbits that pass close to the star (see “► [Planetary Migration](#)”). The interpretation that gentle migration in a disk can sometimes dominate is supported by the independent result from NASA's *Kepler* mission that some systems show transits for two or more planets in orbits that must be nearly coplanar.

Variations in the observed times of transits can indicate the presence of additional planets in a system. This approach is especially powerful for systems with multiple transiting planets. With rich data sets covering full cycles of transit time variations, it is possible to derive masses of the planets involved without the need for radial velocity observations, even the masses of planets for which the radial velocity variations would be too small to measure with present techniques.

In principle, if the photometric precision is good enough, it should be possible to use the

detailed shapes and timings of transit light curves to deduce the presence of moons orbiting the planets and even the shape of the planet, such as oblateness due to rapid rotation.

Basic Methodology

A planet and its host star orbit a common center of mass. An orbital solution based on the spectroscopically observed radial velocities of the host star is traditionally called a spectroscopic orbit by astronomers. Although the orbital period and eccentricity are determined unambiguously by a spectroscopic orbit, the observed velocity amplitude of the orbital solution is only the component projected along the line of sight. From radial velocities alone, it is not possible to determine the inclination of the orbital plane to the line of sight, and thus the true orbital amplitude, and therefore the true mass of the companion are ambiguous. In order for planets to transit, the orbit must be oriented nearly edge on to the observer; the actual inclination can be determined accurately from the shape and duration of the transit events. This allows the actual mass of the planet relative to the host star to be determined if a spectroscopic orbit is also available. Moreover, the transits also yield the radius of the planet relative to the star, because the depth of the dip in the light curve depends on the fraction of the area of the stellar disk that is blocked.

In many cases, the accuracy with which the mass and radius of a transiting planet can be determined is limited by uncertainties in the mass and radius of the host star. This problem is worse for stars where the distance is not known and the characteristics of the host star have to be estimated using stellar models and spectroscopic classification of the stellar parameters. If accurate distances are available, the host star characteristics can be constrained more accurately. Recently, the precision of the stellar parameters for the *Kepler* planets was improved using parallaxes data from the Gaia satellite. This allowed to discover a new feature of the super-Earth/mini-Neptune exoplanet population: the Fulton gap (Fulton and Petigura 2018) separating a population of small

radii (more rocky planets) and a population of larger radii (more gaseous planets). Asteroseismology promises to provide very accurate stellar densities, and from that the masses, radii, and even ages can be derived quite accurately with the help of stellar models. But asteroseismology requires essentially continuous highly precise photometric monitoring over many days. NASA's *Kepler* mission has demonstrated that this approach is feasible for solar-type dwarfs brighter than about 11th or 12th magnitude (see “► [Dwarf Star](#),” e.g., Huber et al. 2013). Recently, Kayhan et al. (2019) revisited the parameters of 20 planetary systems for which there was asteroseismology data (mostly from *Kepler*) to find that including these constraints could lead to differences in planetary radii up to 25% (for Kepler-444b-f).

There are two opportunities for isolating the light from a transiting planet, and both rely on separating the light of the planet from the host star in time rather than in space. The two situations are illustrated in Fig. 2. During the secondary eclipse, when the planet is occulted by the star, only the light of the star is observed. This can be compared with the light observed just before and just after the secondary eclipse, when the combined light of the star and the dayside of the planet are observed. The difference gives the light from the planet, which can be mostly thermal emission from the planetary atmosphere at long wavelengths. During the transits, when the planet passes in front of the star, the amount of light

blocked by the planetary atmosphere depends on its opacity. Thus, any variation in the depth of the transits as a function of wavelength follows the variation of absorption in the atmosphere as a function of wavelength. This can reveal the presence of different molecules in the atmosphere, such as water and methane.

If a star is rotating, then there is a systematic variation of the spectrum across the disk of the star due to Doppler shifts, to the blue for the approaching limb (edge) and to the red for the receding limb. As a transiting planet crosses the stellar disk, it blocks some of the light and introduces a subtle variation in the apparent radial velocity. The shape of the velocity curve during transit depends on the apparent angle, λ , of the trajectory of the planet across the stellar disk compared to the axis of rotation and also on the impact parameter, b , as illustrated in Fig. 3. This distortion on top of the orbital velocity is called the Rossiter-McLaughlin effect.

Stellar systems can mimic the shallow light-curve dips produced by transiting planets. For a planet the size of Jupiter transiting a star the size of the Sun, the dip is about 1% deep. Stellar binaries with cool M dwarfs eclipsing stars similar to the Sun (and larger) can produce light curves that are indistinguishable from transiting giant planets. This is because electron degeneracy sets in near the bottom of the main sequence, and the smallest stars have more or less the same size as substellar objects all the way down to giant planets, 100 times less massive. Fortunately,

Transiting Planets,

Fig. 2 Secondary eclipses, when the planet is occulted by its host star, and transit events, when the planet passes in front of the star, both offer opportunities to study the spectra of the planetary atmospheres, as described in the text

TRA0009

Transiting Planets, Fig. 3 The Rossiter-McLaughlin effect for three different trajectories of a transiting planet across the disk of a rotating star. The apparent angle of the trajectory relative to the spin axis is λ , while the impact parameter that measures the displacement of the trajectory

from the center of the stellar disk is b . When the orbit is retrograde, with the orbital motion in the opposite direction to the stellar spin, the velocity distortions are nominally mirror images of the examples shown

eclipsing binaries are easy to distinguish from transiting planets, because the amplitude of the orbital velocity is much larger and therefore easy to detect spectroscopically. If the photometric precision is good enough, it is also possible to detect brown dwarf and massive planets by the ellipsoidal variations that they induce due to gravitational distortions of the stellar shapes combined with Doppler boosting (also known as relativistic beaming) in the light curves outside of eclipses.

Another source of astrophysical false-positives that mimic transiting planets is grazing eclipsing binaries where the dips in the light curves are shallow because only a tiny fraction of the area of each star is blocked. These imposters are also easy to identify with spectroscopy, especially when the spectra of both stars are visible in the first observation.

Astrophysical false positives composed of fainter eclipsing binary systems contaminating the light of separate stars are more difficult to identify. The contamination by background eclipsing binaries is worse for surveys with poorer spatial resolution and larger pixels. Follow-up observations with high spatial resolution can often pinpoint the offending neighbor. The most

difficult cases are hierarchical systems where the eclipsing binary is physically associated with the target and therefore is too close to be resolved spatially.

Wide-angle ground-based surveys for transiting planets are magnitude limited; every star in the field of view is analyzed. Giant stars can amount to as much as half of the observed sample, despite the fact that they are relatively short-lived and therefore rare in the solar neighborhood, because they are more luminous and can be seen at much larger distances than dwarfs. When follow-up observations show that a transiting planet candidate is a giant star, it is usually assumed that it must be a blend with an eclipsing binary.

The initial enthusiasm for detecting transiting planets with wide-angle ground-based photometric surveys was quickly tempered by the very high rate of astrophysical false positives, typically more than 90%, that required major campaigns of follow-up spectroscopy and photometry to sort out the true planets. In contrast, the M_{Earth} survey targets individual M dwarfs, one by one. M dwarfs are already among the smallest stars, so imposters involving eclipses by smaller stars are

not a problem. Hierarchical blends are unlikely as false positives, because there are so few intrinsically fainter eclipsing binaries. The rate of false positives for the CoRoT and *Kepler* missions is somewhere in between that of MEarth and the wide-angle ground-based surveys, mostly because these two space missions observe lists of targets that have been cleaned of giants. This requires extensive ground-based work to prepare the necessary target catalogs. In the case of the *Kepler* mission, the ability to measure displacements of image centroids during transits with a precision as small as a tenth of a millipixel has made it possible to identify most of the background eclipsing binaries using centroid motion (or lack thereof).

For a long time, the ability to measure radial velocities with a precision sufficient to determine masses of small planets in long-period orbits was the main limitation to the confirmation and characterization of potentially habitable rocky planets that transit. However, that recently changed with the arrival of new spectrographs like ESPRESSO. The reflex motion induced on the Sun by the Earth is less than 10 cm/s, and ESPRESSO has already shown its capacity to reach ~ 20 cm/s precisions (e.g., Kunovac Hodžić et al. 2021).

Key Research Findings

Figure 4 plots the masses and radii for the transiting planets published by mid-2021, nearly 1900 in all (it was about a 100, 10 years ago, this figure can also be compared to Fig. 1 to see the progress the field has done), along with the planets in the Solar System. The large population of points in the upper right quadrant of Fig. 4 illustrates the domain of the gas-giant planets, where the planetary radius is expected to be almost independent of mass because of electron degeneracy in the interiors (see the discussion in “► Brown Dwarf”). The actual observed range of radii is larger than expected and is not yet well understood. Three transiting planets similar to Uranus and Neptune have been discovered, with radii quite similar to their counterparts in our Solar System, despite the fact that they are much hotter. The parameter

space of mass and radius between Uranus and Neptune on the one hand and the Earth and Venus on the other is not populated in the Solar System, but is of great interest because planets with masses in the range 1–10 Earth masses (often called super-Earths) may be enough Earth-like to be potential abodes for life, if there is liquid water on the surface and the primordial atmosphere of hydrogen and helium has been replaced by a secondary atmosphere containing molecules such as carbon dioxide, nitrogen, methane, and water. This region of the parameter space, almost empty 10 years ago is now widely populated, thanks to NASA’s *Kepler* mission. The first two examples of transiting planets confirmed in this region were CoRoT-7b and GJ 1214b. The smaller one, CoRoT-7b, appears to be a very hot rocky planet, while the slightly larger one, GJ 1214b, appears to have a substantial atmosphere of hydrogen and helium and thus is more like a mini-Neptune than a super-Earth. One of the major outcomes of NASA’s *Kepler* mission has been to highlight that this population of Super-Earths/Mini-Neptunes is very common (e.g., Hsu et al. 2019).

Although the atmospheres of several giant, mini-Neptune, and even Super-Earth transiting planets have been detected, HD 189733b is still the poster child for atmospheric studies, initially using both the *Hubble Space Telescope* and the *Spitzer Space Telescope* and also using ground-based observations. Spectral features due to water, methane, carbon dioxide, and carbon monoxide have been reported, and the temperature profile from the nightside to the dayside of the planet has been mapped. These results are described in more detail in the entry on HD 189733.

Observations of the Rossiter-McLaughlin effect have now been reported for more than 250 transiting planets (see review by Triaud (2018) and the catalog <https://www.astro.keele.ac.uk/jkt/tepcat/obliquity.html>). These planets are almost all gas giants though thanks to new spectrophotographs (like ESPRESSO), it is now possible to obtain Rossiter-McLaughlin detections for lower mass planets (e.g., recently a super-Earth, see Kunovac Hodžić et al. 2021). Curiously, the first nine systems all showed pretty close alignment between the

Transiting Planets, Fig. 4 Masses and radii for the transiting planets published as of 2021 (<https://exo-planetarchive.ipac.caltech.edu/>), along with the planets in the Solar System (Venus, Earth, Uranus, Neptune, Saturn, and Jupiter). Comparing this figure with Fig. 1 illustrates the progress made from 2007: many more planets were

discovered, in particular in the bottom left part of the diagram: where the small possibly rocky planets lie. Most of these new planets were discovered by *Kepler*. The horizontal axis is mass in Jupiter masses (bottom) and Earth masses (top). The vertical axis is radius in Jupiter radii (left) and Earth radii (right)

orbital plane of the planet and the equator of the star as defined by its rotation. The following systems showed a range of misalignments, including some retrograde orbits (e.g., Triaud 2018). The distribution of alignments may be consistent with an evolutionary scenario in which planetary systems form in a disk and thus are initially coplanar, but subsequently the orbits are disrupted by gravitational encounters between planets. The planets that are scattered into orbits that pass close to the star experience tidal forces that tend to circularize the orbit by pulling in the apastron (see “► [Periastron](#)”). The planets that survive in wider orbits are less affected by tidal forces and can retain the eccentricities and inclinations that they received during the scattering era. However, this may not be the only mechanism responsible for the migration of giant planets from the cold outer regions where they formed into the inner regions where they are observed. The *Kepler* mission and more recently the TESS mission have announced several

systems that show multiple transiting planets where all the orbits are within about a degree of being coplanar. Furthermore, a small number of these multi-planet systems have been found to be in mean motion resonance (the ratio of the orbital periods of adjacent planets is a ratio of integers), like the Kepler-223 system (Mills et al. 2016) and the TRAPPIST-1 system. Presumably, these systems have not been disturbed from their initial flat geometry dictated by the protoplanetary disk from which they formed, and the migration process must have been gentle. The resonance configuration of some of these systems is also thought to be an outcome of a smooth migration within the disk. To reproduce the ratio of observed resonant systems over all the multi-planet systems, 95% of resonant chains have to be disrupted by the end of the disk phase (Izidoro et al. 2017). On a related note, the *Kepler* data also showed that there is an excess of period ratios that are just slightly larger than some resonances, as though the systems were

formed in these resonances and slightly departed from them over time (e.g., Fabrycky et al. 2014). This feature occurs naturally when resonant planets undergo dissipation (like tides) which damps the eccentricities. Instabilities occurring when the protoplanetary disk dissipates and dissipative processes can therefore disturb the resonant chains naturally formed by migration in the disk. Another remarkable characteristic of the multi-planet systems discovered by *Kepler* is that all the planets within each system appear to be similar in sizes and regularly spaced (like peas in a pod, Weiss et al. 2018). Planetary formation and evolution models help understanding these trends (e.g., Mishra et al. 2021), although there are still open questions. *Kepler* 9 is the first system of planets to show convincing evidence for transit time variations. The two outer planets are very close to a 2:1 mean motion resonance, with periods of 19.2 and 38.9 days. The observed variations in transit times are sufficient by themselves to confirm the planetary nature of the transits. This discovery illustrates the potential for confirming small planets enabled by continuous photometric monitoring over many months and even years.

Future Directions

The *Kepler* mission monitored a field of view that covered only 100 square degrees, just one part in 400 of the entire sky, and CoRoT covered even less area of the sky. To identify the best transiting systems for the confirmation and characterization of small planets, especially ones in their Habitable Zones, it is necessary to survey the entire sky for the nearest and brightest examples. This is what the Transiting Exoplanet Survey Satellite (TESS) has been doing since 2018. By the end of June 2021, TESS has confirmed 131 planets (around 70 new ones) and counts more than 4000 planetary candidates. Since the beginning of 2020, the Swiss satellite CHEOPS has also contributed to better characterizing planets around bright stars. These two missions are ongoing and will contribute significantly to the deeper understanding of

planetary systems. Another example of such missions is PLATO, which has been selected as an ESA M-Class mission to be launched in 2026. In particular, PLATO will determine the radii of the planets with extreme precision and astero-seismology measurements will allow to put exquisite constraints on the age of the system. PLATO has also been designed to find Earth-size planets orbiting at 1 AU from a Sun-like star. Planets smaller than Neptune can have a wide range of compositions and structures and atmospheres, and using just the observable mass and radius to distinguish between different possibilities remains a challenge. However, with the spectrograph ESPRESSO which can measure or refine the masses of the new TESS or CHEOPS planets, the characterization of the population of exoplanets will improve in the years to come. Furthermore, the James Webb Space Telescope (to be launched on December 2021) will allow to probe the atmosphere of some transiting Habitable Zone planets (see “► [TRAPPIST-1 System](#)” and “► [Planet Characterization: Transmitted](#)”), which is going to mark the beginning of an exciting era.

Translucent Interstellar Clouds

Steven B. Charnley
Solar System Exploration Division,
Astrochemistry Laboratory, Greenbelt, MD, USA

Definition

A translucent interstellar cloud is one that has visual extinction intermediate between that of a ► [diffuse cloud](#) and that of a dense ► [molecular cloud](#). Despite the importance of photochemical processes over much of their extent, translucent clouds contain significant molecular column densities. Translucent clouds can be studied both in molecular absorption and emission lines. This term is also used to describe lines of sight through the diffuse edges of dense clouds.

Transport, Biological

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Definition

Transport refers to the exchange of molecules across cell membranes. There are two types of biological

transport, passive and active. Diffusion or passive transport is a kind of transport by which ions or molecules move along a concentration gradient, from an area of higher concentration to an area of lower concentration. In moving substances across a biological membrane, a passive transport may or may not need the assistance of a membrane protein (carrier). Carrier-mediated transport shows a characteristic saturation effect. Passive transport does not require energy. In contrast, active transport is responsible for the movement of ions and molecules in and out of a cell across a selective semipermeable cell membrane against a concentration gradient. In this case, chemical energy is required because osmotic work has to be performed. Transport and ► [energy conservation](#) are intimately related (see ► [“Bioenergetics”](#)).

TRAPPIST-1 System

Emeline Bolmont and Martin Turbet
Department of Astronomy, Université de Genève,
Versoix, Switzerland

Keywords

Exoplanets · Transit · Habitable zone ·
Habitability · Atmospheres · Characterization

Definition

TRAPPIST-1 is an extraordinary planetary system whose discovery was announced in 2016–2017. The system hosts at least seven transiting planets, which orbit very close to a nearby very small star (only 9% the mass of the sun). Among these seven planets, three of them are in the classical Habitable Zone, defined as the region around a star where a planet with the right atmosphere can sustain surface liquid water. This system is known to have an exquisite precision in terms of the radii and masses of the planets, which makes it the system with the best constraints after our own solar system. Finally, the planets of this system are excellent targets for atmospheric characterization, for instance with the James Webb Space Telescope and ELT instruments.

Overview

TRAPPIST-1 is a remarkable planetary system, with at least seven planets in a compact configuration orbiting a small star. The farthest detected planet is at a distance of about 6% the Earth-sun distance. This system is being and will be intensively studied due to its richness for the following reasons: (Gillon et al. 2017) it hosts planets which could harbor surface liquid water, (Gillon et al. 2016) it has an interesting dynamical configuration, shaped by its history and its interactions with the host star, (Agol et al. 2021) the densities of the planets are now known to have an exquisite precision and were found to be very Earth-like and to share a very similar interior composition, and (Ducrot et al. 2020) the atmospheres of these planets will be spectroscopically characterized in the near future, with the James Webb Space Telescope (JWST), for instance. Indeed they all frequently transit a very small star, which makes them good targets for transmission spectroscopy.

Basic Methodology

Constraints from Observations

Transits. The system was discovered using the transit method, which monitors the dip in

luminosity coming from the star when a planet passes in front of it. The TRAPPIST-1 system was discovered using a small 60-cm ground-based telescope (TRAPPIST for TRANSiting Planets and Planetesimals Small Telescope) located on the site of La Silla in Chile. In late 2015, this telescope monitored the light coming from a small star and the observed light curves showed some dips. After careful analysis of the signal, Gillon et al. (2016) published the detection of two planets, TRAPPIST-1b and c, with some hints at a third planet in the system.

Motivated by this discovery, subsequent intense monitoring of the system was carried out by the NASA satellite Spitzer in 2016, and the signals which were originally attributed to a potential third planet were actually corresponding to several additional planets in the system (Gillon et al. 2017). The planets were named TRAPPIST-1d, e, f, and g. In the Spitzer data, there was an orphan transit which was attributed to a TRAPPIST-1 h. Using the knowledge of the particular dynamical configurations of the six inner planets, the orbital period of planet h was hypothesized to be around 18 days. And this was later confirmed in Luger et al. (2017), using data from the K2 satellite. Although some orphan transits have been detected in the Spitzer data, they are of low significance and are therefore not attributed to new planets (Ducrot et al. 2020) (Fig. 1).

Transit timing variations. Follow-up observations allowed for better constraining of the properties of the star and its planets, in particular for their radii (e.g., Delrez et al. 2018) and masses (e.g., Grimm et al. 2018; Agol et al. 2021). While the radius of the planet is a natural outcome of the transit method, the masses of the planets were derived using the transit timing variation technique. Transit Timing Variations (TTVs) happen when the orbit of a planet is perturbed from a perfect Keplerian orbit. In the absence of additional planets, the transit of one planet would occur at regular intervals (every orbital period). If there is an additional planet in the system, there will be gravitational interactions which will perturb the orbit, sometimes delaying the transit, sometimes advancing it. These are the transit timing variations. For TRAPPIST-1, the planets are in a very compact configuration and a

TRAPPIST-1 System, Fig. 1 Representation of the orbits of the seven planets. The blue area represents the extent of the Habitable Zone. (Figure adapted from Gillon et al. (2017))

dynamical configuration, which exacerbates the TTVs. Using the TTVs for all the planets, models can be run to infer their masses. Grimm et al. (2018) showed, using this technique, that the planets have a composition somewhat similar to the Earth and that some of them may even have a large reservoir of volatiles (i.e., water). Recently, 447 transit times over 4 years of observations were compiled to derive even more precise masses (Agol et al. 2021). These masses allowed for better constraining of the range of possible compositions of the planets.

Transit spectroscopy. Measuring the transit depths of the planets at different wavelengths can be very instructive. If the instrumental biases are perfectly removed and if there is no contamination from stellar activity, the dependence of the transit depth (or planetary radius) with wavelength is due to the absorption from the planets' atmosphere. This technique is called transit spectroscopy (see also planet characterization: transmitted light). Transit spectra of TRAPPIST-1b to h were measured in the mid-infrared with Spitzer (Delrez et al. 2018; Ducrot et al. 2020) and in the near-infrared with the WFC3 instrument of the Hubble Space Telescope (De Wit et al. 2016, 2018; Lionel Garcia and Michael Gillon, private

communication). The results are discussed in the section “Key Research Findings.”

Constraints from Simulations and Theory

Parallely to the efforts to observationally constrain both the structure and the atmosphere of the planets, many theoretical studies aimed at understanding the system.

Planet formation and dynamics. The formation of the system and the water delivery to the planets was investigated using models that account for N-body dynamics and the effect of the disk. Planets embedded in protoplanetary disks interact with the gas and dust and this can lead to migration (in most cases, an inward migration), which can lead to collisions and ejections. These codes aim at reproducing this migration in order to better understand the system's current dynamical state. Simulations of the tidal N-body dynamics of the system have also been performed to try to constrain today's dynamical state, for instance to understand the particular resonant configuration of the system (e.g., Papaloizou et al. 2018), or to infer the rotation state of the planets and the resulting tidal heat flux (e.g., Turbet et al. 2018).

Water loss. Some other theoretical studies also tried to estimate the amount of water lost by the planets during the long hot pre-main sequence phase of the host star. The evolution of a small star like TRAPPIST-1 is different from the evolution of a sun-like star. The pre-main sequence is the early stellar evolution phase during which the star contracts and its luminosity decreases. When the temperature in the center of the star reaches the temperature allowing for hydrogen fusion, the star enters the main sequence and its luminosity becomes constant. The pre-main sequence phase for a small star like TRAPPIST-1 lasts much longer than for a sun-like star. This means that a planet in the Habitable Zone today initially received levels of insolation that were too high to sustain surface liquid water. During that long pre-main sequence phase, all the water is therefore in gaseous form in the atmosphere and is submitted to the high-energy radiation (X and Extreme UV) coming from the star. These radiations can break up the molecules of water and make the hydrogen and oxygen atoms escape the gravitational pull of the planet (Bolmont et al. 2017).

Atmospheric escape can also be driven by magnetic interactions (e.g., Garraffo et al. 2017).

Climates. Many theoretical studies aim at (Gillon et al. 2017) constraining the planets' atmospheres and (Gillon et al. 2016) assessing the planets' potential to host surface liquid water. These studies are usually done with climate models, either 1D (only one globally averaged vertical column of the atmosphere is modeled) or 3D (altitude, latitude, and longitude are modeled; see Turbet et al. 2020b). These models can also be coupled with photochemical models in order to account for the influence of the stellar radiation on the chemical composition of the planets' atmosphere (e.g., Chen et al. 2021). For different assumptions on the atmospheric composition, one can compute the size of the planet and how it varies with wavelength and rule out certain compositions, for instance, and one can also test the capacity to sustain surface liquid water.

Key Research Findings

Using all the constraining methods detailed in the previous section, many discoveries were made about the system.

Dynamics and Compositions

This system is extraordinary concerning its dynamical configuration: the planets are close to mean motion resonances. Just like the three inner satellites of Jupiter which orbit the planet with period ratios of 4:2:1 (while Io orbits Jupiter 4 times, Europa orbits it twice, and Ganymede once), the planets of TRAPPIST-1 orbit their stars with ratios of 24:15:9:6:4:3 (Luger et al. 2017). Not only are the planets in mean motion resonances, each set of three planets is also in a three-body resonance called a Laplace resonance (another similarity to the Jovian system).

This particular orbital configuration is thought to be an inheritance from the formation stages and the following tidal evolution. One possible formation pathway is migration in the disk from outside the snowline (the radial position in the disk where water condenses from gas to solid). Indeed, while the protoplanets are still embedded in the gas and

dust protoplanetary disk, they can migrate due to the disk interactions. In that scenario, the planets are initially formed far from the star, out of the snowline, and are therefore water-rich. One outcome of several planets migrating in a disk is the creation of these long resonant chains of planets (e.g., Izidoro et al. 2017; Coleman et al. 2019). The majority of these chains destabilize when the disk dissipates, but some of them survive, and TRAPPIST-1 is one of the best examples (e.g., Tamayo et al. 2017). Another formation pathway is in situ formation (MacDonald and Dawson 2018). In that scenario, the planets only migrate a small distance and form close to their present location. Therefore, they do not all originate from outside the snowline and are hence expected to have a drier composition. In situ formation can also reproduce the main characteristics of the system, like the mean motion resonances and the three-body resonances. The main difference between the two pathways is the theoretical amount of water that makes up the bulk of the planet: water-rich for the long-range migration and water-poor for the in situ formation.

For the systems which survive the disk dissipation, tidal dissipation can later play a role by also driving migration. Migration changes the distance between the planets and, in particular, tidally induced migration can also explain the more specific three-body Laplace resonance (e.g., Papaloizou et al. 2018). It was also shown in Turbet et al. (2018) that tides lead to a quick synchronization of the rotation of the planets and a damping of the eccentricities. Just like the Jovian satellites, the small eccentricities are enough to drive significant tidal heating in the close-in planets and Earth-like levels of heating for the Habitable Zone planets (e.g., Barr et al. 2018; Makarov et al. 2018; Bolmont et al. 2020). Although this level of heating should not have a major impact on the climates of the HZ planets, it could influence the surface temperature of the potential cold traps on the nightside of the planet where the gases that make up the atmosphere can condensate or it could also influence the depth of an eventual subsurface ocean (see Turbet et al. 2018).

Thanks to the method of the Transit Timing Variations recently used in the Agol et al. (2021)

study (see section “[Basic Methodology](#)”), the planetary masses are now known with exquisite precision. Contrary to the previous study of Grimm et al. (2018), where some compositional differences have been hypothesized, these new results show that all planets can in fact be described by a single interior composition (see Fig. 2): either an Earth-like composition but slightly depleted in iron (21% vs 32% for the Earth) or an Earth-like composition but with a light-element enhancement (e.g., a surface water layer).

However, the latter scenario is not favored. In fact, using the mass-radius relations for planets with steam atmospheres (Turbet et al. 2020a; Agol et al. 2021; Acuña et al. 2021), these new mass measurements show that the inner planets are most likely to be dry. This is compatible with several theoretical studies (e.g., Bolmont et al. 2017; Bourrier et al. 2017; Garraffo et al. 2017; Dong et al. 2018), which showed that the atmospheric escape for the inner planets of the system is a very efficient process. The outer planets’ masses and radii are compatible with some non-negligible amount of water, which could be a clue that they indeed formed outside the snowline and

migrated in and that they did not lose their water as the inner planets did.

Atmospheres and Habitability

One of the most fascinating features of the system is that three planets are located inside the Habitable Zone. This system is ideal to deepen the understanding of the concept of habitability with planets both in the Habitable Zone and outside of it. Just as understanding Mars and Venus helped us fathom the specificities of Earth’s climate, investigating all the planets of the system will help us comprehend the potentially habitable planets of TRAPPIST-1.

The investigation on the atmospheres of the TRAPPIST-1 planets has been done observationally and theoretically with climate simulations, whether 1D or 3D. As explained in the “[Basic Methodology](#)” section, the system has now been observed with a large number of astronomical observatories (see Turbet et al. 2020b and references therein). Observations by the **Hubble Space Telescope** (HST) (de Wit et al. 2016, 2018; Wakeford et al. 2019) and Spitzer (Delrez et al. 2018; Ducrot et al. 2020) were used to perform pioneering transit spectroscopy measurements of

TRAPPIST-1 System,
Fig. 2 Mass-radius relationship for the TRAPPIST-1 planets based on TTVs analysis. The contours show the mass and radius of the planets. The full lines represent theoretical mass-radius relations for different assumptions. (Figure adapted from Agol et al. (2021))

the planets. These observations allowed for the ruling out of the presence of clear light-weight (i.e., low metallicity) hydrogen-dominated atmospheres for all TRAPPIST-1 planets, with a variable degree of certainty depending on the planet. This result is illustrated in Fig. 3, which shows that the expected spectral variations of a cloud-free H_2 -dominated atmosphere (mainly due to absorption by H_2O and CH_4) are much larger than those individually observed by HST (from 1.1 to 1.7 microns) and/or Spitzer (between the two observation channels, at 3.6 and 4.5 microns).

Data could in principle still be in agreement for most planets with a hydrogen-dominated atmosphere with either high-altitude clouds/hazes

and/or with heavy weight (due to a very high metallicity).

However, the presence of hydrogen-rich atmospheres (whether it is cloudy or not; whether it has a low or high metallicity) should produce a large dispersion of the density between the planets (Turbet et al. 2020a) – because small variations in mass, temperature, metallicity, and cloud/haze position of the hydrogen atmosphere should produce large variations in radii – which can now be ruled out using the most accurate density measurements available (Agol et al. 2021).

In sum, this means that the planets of TRAPPIST-1 are not hydrogen-dominated and

TRAPPIST-1 System, Fig. 3 Transit spectra for the TRAPPIST-1 planets: the points correspond to the measurements coming from different space telescopes (Kepler

(K2), Hubble Space Telescope (HST), and Spitzer) and the blue curves correspond to model spectra of (cloud-free) hydrogen-dominated atmospheres

could therefore be composed of heavier molecules like N_2 , CO_2 , H_2O , O_2 , or CH_4 , or not have an atmosphere at all.

Now that a primitive atmosphere has been ruled out, can any of the planets of TRAPPIST-1 sustain liquid water at their surface? This would mean that 1) they have an atmosphere, 2) they have some water, and 3) this water can be liquid at the surface.

The issue with 1) and 2) is that during the long pre-main sequence of the star, the high luminosity and the high energetic radiations could have driven significant atmosphere loss and therefore water loss. The main conclusions of the review of Turbet et al. (2020b) concerning the existence of different atmospheres on the planets are given below:

Hydrogen atmospheres. Given the constraints on the masses and radii of the planets (e.g., from Agol et al. 2021), the constraints based on HST and Spitzer transit spectra (e.g., De Wit et al. 2018; Ducrot et al. 2020), and the constraints coming from atmosphere escape models (e.g., Bourrier et al. 2017), it is unlikely that the planets were able to retain a hydrogen atmosphere (either clear or cloudy/hazy). The detailed justification of this rationale is given in Turbet et al. (2020b).

Water envelopes. From the masses and radii of the planet, it is also possible to infer the content of water of the planet (under certain assumptions on the rocky core): the inner planets of TRAPPIST-1 (b to d) are likely to have a low water content (a water mass fraction below 10^{-3}) and the outer planets (e to h) could have water mass fractions as high as a few % (Agol et al. 2021). A drier inner system and a wetter outer system is compatible with (Gillon et al. 2017) a formation farther away in the disk and therefore a water-rich initial composition and (Gillon et al. 2016) the hydrodynamic water loss calculations of Bourrier et al. (2017). They found that the inner planets lose their water since their formation up to the present day, which can amount to between 25 and 90 Earth oceans lost. However, if the outer planets stop losing water when they reach the Habitable Zone, they lose much less water (less than 3 Earth oceans).

Future Directions

One of the features that makes this system particularly interesting is the future observation prospects of their atmospheres. Indeed, thanks to the proximity of the system to Earth, thanks to the size of the host star and the short orbital periods of the planets, it will be possible to probe the atmospheres of the TRAPPIST-1 planets. For instance, using transit spectroscopy with the James Webb Space Telescope (JWST), it will be possible to put constraints on these atmospheres. The system is the target of two proposals the Guaranteed Time Observations Programs in Cycle 1 and following the call for proposals for the General Observer Programs in Cycle 1, three proposals targeting the system's planets were accepted (<https://www.stsci.edu/jwst/science-execution/approved-programs/cycle-1-go>). The system is the target of two proposals in the Guaranteed Time Observations Programs in Cycle 1 and following the call for proposals for the General Observer Programs in Cycle 1, three proposals targeting the system's planets were accepted.

Synonyms

Basaltic flood plains; Continental Flood Basalt Provinces; Flood basalt; Traps

Acronyms

CFB

Definition

Trapps is a Swedish word for “stairs” a reference to the step-like topography of the basaltic sequences. Most flood basalts erupted subaerially, hence the name of Continental Flood Basalt or CFB but they can erupt also as a part of an oceanic plateau, and together forming the group of large igneous provinces (LIP). Flood basalts form thick (500 to more than 3000 m thick) volcanic sequences that cover large areas, up to 1.5 million km² in the case of the largest one, the Siberian Traps. Most authors believe that the trapps formed through the melting of large mantle plumes. The distribution of volcanism is primarily controlled by existing lithospheric and crustal weaknesses (Jerram and Widdowson 2005). The main phase of volcanism consists of repeated episodes of eruption of tholeiitic basalts that generate large tabular flows and flow fields in a relatively short period of time (1–5 Ma). The overall duration of flood volcanism last 5–10 Ma. The volume of igneous rocks erupted by the 16 identified CFB and oceanic plateaus formed in the last 500 Ma on Earth exceeds the total output of present-day mantle plumes and even possibly exceeds over short times the entire crustal production at mid-ocean ridges, making CFB major geodynamic events in the Earth history (Courtilot and Renne 2003). Plausible chronological relations exist between CFB and major biological and geological crisis such as mass extinctions and oceanic anoxia events, suggesting that the large volume of lava flows, associated toxic sulfur gases and CO₂ emission in the atmosphere produced by fires could have played a role in those events (Courtilot and Renne 2003).

Definition

In chemistry, the triple point of a substance is the point in a pressure/temperature regime under which a compound exists in all three states of matter in thermodynamic equilibrium: gas, liquid, and solid. The triple point of water occurs at 273.16 K (0.01 °C) and a vapor pressure of 611.73 Pa. As the temperature of the triple point of water is an exact defined value and not a measured quantity, the triple point of water can be used to define the Kelvin.

Triton

Therese Encrenaz
LESIA, Observatoire de Paris – Section de
Meudon, Meudon, France

Keyword

Neptune's satellites

Definition

Triton is Neptune's largest satellite. It was discovered in 1846, a few weeks after ► [Neptune](#). Triton's average distance to Neptune is 354,800 km, or 14 planetary radii. Triton's orbit is nearly circular but shows a very high inclination (157° , with respect to the normal to Neptune's equator, so that it revolves in retrograde motion around Neptune), which suggests that the satellite was captured. Triton's high inclination, together with Neptune's obliquity (29°), leads to very large variations of the latitude of the subsolar point ($\pm 52^\circ$). As a result, Triton exhibits the largest seasonal effects known in the solar system. Triton, as most of the outer satellites, is in synchronous rotation with its planet: it always turns the same face toward Neptune.

Overview

Prior to the encounter of the Neptune system by the Voyager 2 probe, little was known about

Triton's atmospheric and surface properties. Methane and nitrogen ices had been detected from near-infrared ground-based spectroscopy, which suggested the presence of a stable N_2 atmosphere, but the surface pressure was unknown.

Most of our knowledge about Neptune's largest satellite has come from the Voyager 2 observations. Precise determinations of Triton's diameter (2700 km), density (2.1 g/cm^3), surface temperature (38 K), and surface pressure (14 microbars) were retrieved from Voyager 2 data. With an albedo of 0.76, Triton is among the brightest solar system bodies, and its surface temperature is the lowest ever measured. Nitrogen was found to be the main atmospheric component, with traces of methane at the 0.01% level. The presence of a stable atmosphere, which is unusual on such a small object, can be explained by the low temperature of the satellite, which increases the escape velocity.

Triton's Surface and Internal Structure

Voyager's observations mostly covered the southern hemisphere of Triton. The images revealed a bright, extended polar cap around the South Pole. North of this region, rugged terrain shows a pattern of intercepting ridges, which appear as the remnants of past tectonic activities. There are few craters, which implies that the surface is relatively young. The equatorial region is more cratered and might be 3 billion years old (Fig. 1).

In the bright region around the South Pole, Voyager detected dark trails rising vertically up to an altitude of 8 km and then trailing to the west side over more than 100 km. The most common interpretation of these plumes is active ► [cryovolcanism](#). The outgassed products would be mostly N_2 and CH_4 , which freeze as they reach the surface. Some dust is also present, presumably hydrocarbons, that contributes to the dark color of the plumes. The cryovolcanic activity could be driven by the strong seasonal thermal variations.

In addition to N_2 and CH_4 ices, ground-based near-infrared ► [spectroscopy](#) allowed the detection of a variety of ices: H_2O , CO_2 , CO , and NH_3 . Due to seasonal effects, N_2 and CH_4 are transported alternatively from one polar cap to the

Triton, Fig. 1 The surface of Triton as observed by the Voyager 2 spacecraft in 1989

other. In the atmosphere of Triton, they play a role similar to CO_2 and H_2O on Mars: large-scale dynamical motions are induced by seasonal transfer, as shown by the dynamical motions of the plumes.

Very little is known about the internal structure of Triton. Theoretical models propose a central core of metals and rocks, surrounded by a mantle of water ice, covered by a mixture of various ices.

Triton's Atmosphere

The atmosphere of Triton extends up to an altitude of 800 km. The [troposphere](#) extends up to an altitude of 8 km where the temperature is minimum. The temperature increases again in the thermosphere, to reach a value of 95 K at an altitude of 400 km, where ionization takes place. Hydrocarbon hazes and nitrogen clouds have been identified by Voyager in the southern hemisphere, presently illuminated by the Sun.

In the 1990s, new observations of Triton's surface have been obtained from the ground using the stellar [occultation](#) technique. The atmosphere was found to be more dense than reported by Voyager 2, and the surface temperature increased by 5% between 1989 and 1998. This increase is the sign of an unusually warm summer. A possible reason might be a change in the ice composition of the surface, leading to a lower albedo, or, alternatively, a reddening of the surface due to the geyser activity.

Origin of Triton

What is the origin of Triton? The high inclination of its orbit suggests that it is a captured object. Triton's surface and atmosphere show a striking similarity with [Pluto](#), in terms of physical properties (surface pressure and temperature), atmospheric composition (dominated by N_2 with traces of CH_4), and surface composition (ices of N_2 , CH_4 , CO , CO_2 , H_2O , and NH_3). These similarities strongly suggest that Triton might be a trans-Neptunian object. However, the mechanism of Triton's capture remains unexplained, as the probability of such a capture is quite small.

Trojans (Asteroids)

Maria Antonietta Barucci¹ and Sonia Fornasier^{1,2}

¹LESIA, Observatoire de Paris, Université PSL, CNRS, Université Paris Cité, Sorbonne Université, Meudon, France

²Institut Universitaire de France (IUF), Paris Cedex 05, France

Keywords

Asteroids · Jupiter

Synonyms

Lagrangian point objects

Definition

Trojans are all the objects located in the L_4 and L_5 ► [Lagrangian points](#) of the orbit of a planet around the sun or of a large satellite around a planet.

Overview

The objects located in the L_4 and L_5 Lagrangian points of a planet's or large satellite's orbit are called Trojans. The Lagrangian points of stability, L_4 and L_5 , are located at the 1:1 sun-planet (or planet-satellite) resonance and lie 60° of heliocentric (or planetocentric) ecliptic longitude ahead (L_4 , leading point) and 60° behind (L_5 , trailing point) the larger body. The Trojan objects have sufficient dynamical stability to survive over the age of the solar system. The term Trojans originally referred to the ► [asteroids](#) populating the Lagrangian points of Jupiter's orbit, but to date Trojan objects have been also discovered in the orbits of Earth, Mars, Uranus, and Neptune, and Trojan moons are known to orbit at the Lagrangian points of Tethys and Dione, two midsized moons of Saturn.

The numbers of discovered Trojans is close to 10,000 to date, and the vast majority of them populate the L_4 and L_5 swarms of Jupiter. Only 10 Trojans were discovered for the inner planets (1 for the Earth, 9 for Mars), 29 for Neptune, and just one for Uranus. However, the real population of Trojans is expected to be much larger, with millions of objects populating the Jupiter and Neptune L_4 and L_5 swarms. The Neptune Trojan population is expected to be 20 times larger than that of Jupiter, despite the relatively few discovered objects to date.

While the dynamical characteristics are quite well determined, the physical properties of the Mars, Jupiter, and Neptune Trojan populations are not yet well known.

Concerning the Mars Trojans, seven of them form an orbital cluster and share similar olivine-rich composition that may be consistent with an origin from impact ejecta from Mars. However, other Mars Trojans have a different mineralogy, suggesting that they did not form in their current locations.

For the Jupiter Trojans, a number of surveys in the visible and infrared range permitted the casting of light on their physical properties and composition. These asteroids have low albedo and usually a red spectral behavior (the reflectance increasing with the increasing wavelength) consistent with an organic-rich composition. Two models have been proposed for the origin of the Jupiter Trojans. The first classical model considers that the Trojans were planetesimals formed in the vicinity of Jupiter's orbit and captured at the stable points. The other model also invokes the capture of Trojans, but from a more distant disk. This primordial transneptunian disk is also the source of the ► [Kuiper belt](#) or transneptunians objects. This latter dynamical modeling suggests a genetic relation among transneptunian objects and Jupiter and Neptune Trojans. This potential link is strengthened by the fact that both Jupiter and Neptune Trojans have colors and surface composition very similar to part of the transneptunians population in the outer solar system. All these objects are believed to have formed at heliocentric distances in a region rich in frozen volatiles.

Important advances on the knowledge of Jupiter Trojans' physical properties are foreseen in the future, thanks to the ground-based and space new generation telescopes (LSST, ELT, GAIA, JWST) and to the Lucy mission, a NASA discovery mission that will visit six Jovian Trojans between 2025 and 2033.

True Polar Wander, Theory of

Daniele L. Pinti

Geotop, Research centre for the dynamics of the Earth system, Université du Québec à Montréal, Montréal, QC, Canada

Synonyms

[Polar shift](#); [Polar motion](#)

Acronyms

TPW

Definition

True polar wander is the rotation of a planet or moon with respect to its spin axis, causing poles to change position or “wander.” The theory states that the development of an unequal distribution of mass in the interior or on the surface of the planet causes a change in the axis of rotation. Causes of TPW include postglacial crustal rebound, asteroid impacts, change in the core-mantle boundary topography, and mantle avalanches (avalanche of cold, dense crustal slab material into the lower mantle). Earth has undergone several periods of polar wander in the past resulting in cumulative magnitudes of up to 75°. Offset position of paleopolar deposits with respect to Mars poles suggests that the Red Planet has undergone TPW, possibly driven by shift or large-scale volcanism on Tharsis region. TPW might have happened on ► [Enceladus](#) and ► [Europa](#) (up to 80°).

Turbidite

Nicholas Arndt
Maison des Géosciences, LGCA, Université
J. Fourier, St-Martin d'Hères, France

Definition

A turbidite is a sediment deposited from a turbidity current, which is a current of sediment-charged water that moves under the force of gravity; it is therefore the product of a mass flow type of sediment movement.

In turbidity currents, sediment grains are eroded and suspended (and thus transported) by turbulence, in contrast to debris flows or grain flows, the other common types of mass flow processes. Importantly, the sediment plays the

essential role in turbidity currents because they impose a density to the flow, which drives it downslope. The water only acts as dilutant, passive lubricant, and induces turbulence. During flow, the turbidity current “tunnels” through the bottom of a standing water column; it slows down (and thus gradually diminishes in turbulence and therefore drops sediment) when the gradient of the slope decreases. Because turbidity currents accelerate near the shelf margin, they can reach large dimensions, and flow steadily over inclined continental slopes, their runout distances can reach many hundreds of kilometers on the flat abyssal plains.

Turbidity currents are the principal transporting agents on continental margins. They remove sediments from the shelf in incised canyons and transport them downslope to the continental rise. There, turbidites accumulate and may form over time strata many km thick.

The sequence deposited from a single turbulent event is called a Bouma sequence and is anywhere from a few cm to several m thick. Provided that the generating turbidity current had a full range of clasts and grain sizes available, a Bouma sequence will be fining upward, often beginning with a granule or coarse-sand-grained layer at the base and pass through the sand to silt and shale at the top, each section also displaying characteristic sedimentary structures generated during a particular hydrodynamic flow phase.

Turbidites have been well documented in Archean supracrustal sequences, such as the Fig Tree Group of the ► [Barberton Greenstone Belt](#). The oldest turbidite has been identified in the 3.8-Ga-old ► [Isua Supracrustal Belt](#) of West Greenland, indicating that deep oceans were already present on the early Earth.

Turbulence (Planetary Disks)

Avi M. Mandell

NASA Goddard Space Flight Center, Greenbelt,
MD, USA

Keywords

Accretion · Migration · Planet formation

Definition

Turbulence is the state of hydrodynamic motion characterized by a chaotic and random direction of fluid flow on short timescales. Turbulence is thought to play a major role in the movement of material in gaseous ► [protoplanetary disks](#) in the radial direction by contributing to the fluid viscosity and leading to the accretion of gas onto the central star and in the vertical direction through stirring due to turbulent eddies. Understanding the effects of turbulence in disks is important in theories of planetary migration (as it can, e.g., lead to a random walk component in ► [planetary migration](#)), the efficacy of accretion from mm- to meter-sized bodies, and the global evolution of disks.

Overview

Turbulence occurs in fluids when the diffusion of momentum within a fluid is inefficient enough to cause the smooth flow of material (called a laminar flow) to become chaotic in direction and amplitude. This causes structures, such as eddies and vortices, to form in the fluid on both large and small spatial scales, leading to increased mixing within the fluid and an increase in energy and momentum convection (“fluid friction”). The efficiency with which the turbulent motions transfer momentum and energy between fluid particles can be summed up in a parameter called the “eddy viscosity.” The level of turbulence within a fluid can be estimated from the Reynolds number, a ratio of the inertial and viscous forces at work.

As material in a ► [protoplanetary disk](#) circles its central star, the gaseous component of the disk functions as a viscous fluid. The gas rotates in a laminar flow if the Reynolds number is low enough, but most likely, turbulence is present at some level. The turbulent motions in the disk may serve to stir up mm-sized bodies in the disk, enhancing collisions and leading to an increased particle accretion rate. However, turbulence may also cause accretion to stall if the stirring does not allow midplane densities sufficient for gravitational instabilities to form.

The mechanism for the growth of objects between 1 mm (where they are dominated by aerodynamic drag and fall rapidly into the Sun) and 1 m in size is one of the unsolved problems in planetary formation, and therefore the role of turbulence on accretion is of great interest. However, the source of turbulence in astrophysical accretion disks is still uncertain. The existence of accretion onto young stars demonstrates that turbulent viscosities cause material to spiral in, but pure molecular viscosity (caused by chaotic interactions between neutral molecules) is not sufficient. Most likely, a mechanism, such as the magneto-rotational instability (MRI), generates the needed turbulence, but this is an active area of research.

Turbulence, Interstellar

Steven B. Charnley

Solar System Exploration Division, Code
691, Astrochemistry Laboratory, NASA Goddard
Space Flight Center, Greenbelt, MD, USA

Keywords

Interstellar medium · Star formation

Definition

Interstellar turbulence describes the compressible and hydromagnetic bulk flow of interstellar gas on many physical scales.

Overview

Unlike the incompressible turbulent flows encountered in terrestrial physics, which are generally subsonic and hydrodynamic, turbulence in the interstellar medium is supersonic, highly compressible, and magnetic. The driving forces of interstellar turbulence are nonuniform and non-homogeneous, involving, for example, supernova blast waves and winds from young stars. Numerical simulations indicate that interstellar supersonic turbulence is dissipated in ► [shock waves](#) and forms gravitationally unstable density enhancements, which collapse to form stars. In dense ► [molecular clouds](#), observed scaling relations between density and ► [linewidth](#) and size (► “[Larson’s Law](#)”) are consistent with the presence of turbulent density and velocity fields.

UKCA

Definition

The UK Center for Astrobiology was set up in 2011 as a virtual center to contribute to astrobiology research, education, and outreach.

Its research has focused on studying life in extreme environments, the limits of life on Earth, and investigating the implications for habitability elsewhere. Work has involved a combination of laboratory-based and theoretical approaches. Examples of this research include efforts to understand how combinations of multiple extremes shape the “boundary space” for microbial cell division, studies on adaptations of life to low temperature, radiation, and saline environments. Work has been undertaken to investigate the molecular basis of microbial adaptations to extremes using –omics methods, for example the metagenomic and proteomic study of life in natural brine environments and in laboratory experiments.

Overview

The UK Center for Astrobiology is interested in using the study of life in extreme environments on Earth to understand the potential habitability of

extraterrestrial environments. In addition to laboratory and theoretical studies, the UKCA has been involved in using data from space missions, including ESA Mars missions and International Space Station experiments (e.g., BioRock), either in collaborative projects or in efforts led by the Center. Beyond our own Solar System, the Center's research on life in extreme environments can be used to inform predictions about the habitability of exoplanets.

International projects have included coordination of the European Union (EU) project, MASE (Mars Analogues for Space Exploration), aimed at examining anaerobic organisms in extraterrestrial analogue environments and leading the microbiology effort of the NASA-funded project BASALT (Biologic Analog Science Associated with Lava Terrains).

Among its research infrastructure projects, the Center has assembled the world's first permanent underground astrobiology laboratory, the Boulby Underground Laboratory. Boulby Mine is an active salt mine in the northeast of the UK that includes over 1000 km of roadways at a depth of ~1 km underground. The mine operates in vast evaporite deposits that are ~0.25 Ga old and were formed in the Zechstein Sea. To date, studies have included: genomic and metagenomic studies of organisms that inhabit brines of differing composition, investigations of the microbiome and biosignatures in Permian salts, analyses of gases associated with Permian salts, the study of life at below-background radiation.

Many of the challenges faced by planetary scientists (such as building small miniaturized instruments that are lightweight, require low energy, and operate in extremes) are also challenges faced by those in the deep subsurface mining sector who want instruments to detect and quantify ore quality, map and study subsurface tunnels and structures, and check underground environments for safety. A deep subsurface mine therefore provides an opportunity to carry out deep subsurface planetary science work in a real commercial setting where ideas can fluidly move from scientists and instrument developers to the mining environment. The Center established a

program called MINAR (Mine Analog Research) which uses the underground work to test instrumentation for planetary exploration and/or deep subsurface work. Since 2013, there have been six analogue campaigns that have involved testing a variety of instruments including those developed for Mars exploration, such as the ExoMars CLUPI (Close-Up Imager), Raman and PanCam emulator, and HABIT instrument. The MINAR program has also been used for basic astronaut training by ESA.

The Center has been involved in a diversity of educational activities. Its astrobiology academy, developed in 2013, has been used for the development of lesson plans and curriculum materials for primary and secondary schools. For example, the Center developed a complete astrobiology transition course for primary to secondary school transition in conjunction with the RAISE (Raising Aspirations in Science Education) in Scotland. The Center has overseen an initiative to take astrobiology into prisons. Life Beyond is a project that engages prison inmates in the design of stations for the surface of Mars and in the process develops their scientific and literary skills. The Center has been involved in university research teaching and has overseen the development of an undergraduate astrobiology course at the University of Edinburgh. The center has worked with the Kalam Center/Abdul Kalam University, India, to develop university astrobiology courses and primary and secondary school astrobiology materials. The Center developed the Mars Mission India program with the Kalam Center which involves Indian students in the development of technology for Mars exploration which they test in the underground astrobiology laboratory.

A full summary of the Center and its activities can be found in Cockell et al. (2018).

Definition

The UK Space Agency, launched in March 2010 and replacing the previous partnership structure of the British National Space Centre, has responsibility for policy and key government budgets for civil space programs. It will contribute to the European Space Agency (ESA) (subscriptions previously funded by the Natural Environment Research Council), the Science and Technology Facilities Council (STFC), the Technology Strategy Board (TSB), and management of major EU space-based projects including GMES (Global Monitoring for Environment and Security). The UK Space Agency negotiates on the UK's behalf on international bodies such as the European Space Agency and is represented at all the key ESA bodies.

Involved in numerous space programs, the UK takes a major role in robotic exploration of the solar system. Currently it is the second largest contributor to the ESA ExoMars program. At the Council of Ministerial meeting at ESA in November 2008, an agreement was signed between the UK and ESA to establish a permanent ESA site at the Harwell Science and Innovation

Campus in Oxfordshire. This facility opened in July 2009.

In 2014, the UK Space Agency had around 50 employees.

Definition

UltraCarbonaceous Antarctic Micrometeorites (UCAMMs) are submillimeter-sized extraterrestrial particles with high concentration in carbonaceous material. They most probably originate

from surface of icy parent bodies from beyond Neptune (i.e., comets).

Overview

By contrast with the many different existing types of ► [meteorites](#), the majority of micrometeorites collected at the Earth's surface show chemical and mineralogical similarities with a fairly rare class of meteorite – the ► [carbonaceous chondrites](#) – but do not strictly belong to a given class of carbonaceous chondrites. Among the rare types of particles departing from these “chondritic micrometeorites,” some exhibit extremely high bulk carbon content (>25 wt.%) that exceeds by far that observed in carbonaceous chondrites (typically <5 wt%). These rare micrometeorites are referred to as UltraCarbonaceous Antarctic Micrometeorites (UCAMMs).

So far, UCAMMs have been identified in snow and ice samples from Antarctica (Dome Fuji and Dome C) and might be present in the IDP collections from the stratosphere. The center of the Antarctic continent presents unique advantages to recover rare and unaltered interplanetary particles. It is well protected from terrestrial dust contamination (for particles with sizes greater than 10 μm) as the continent itself is surrounded by oceans and the dominant winds are blowing from the center of the continent to the coast, providing a natural shield against terrestrial particles. Dome C is located at 1100 km from the coasts of Adélie Land and Dome Fuji at about 1000 kms from the coasts of Queen Maud Land. Dome C is the location of the scientific station CONCORDIA (75°S, 123°E) operated by the french and italian polar instituts (IPEV and PNRA). The central Antarctic regions' temperatures stay far below 0 °C throughout the year. Trapped at low temperatures (about –50 °C) in layers of ultrapure snow, the micrometeorites are preserved from terrestrial weathering (mechanical constraints and aqueous alteration). Since the terrestrial component is minimal, it is possible to recover from central Antarctic snow rare and well-preserved micrometeorites.

The extraterrestrial origin of UCAMMs is attested by both their (minor) mineral components

that are similar to that of carbonaceous chondrites and by their isotopic compositions. The isotopic composition of UCAMMs from the Concordia Collection exhibits extreme enrichments in deuterium. The bulk D/H ratio of their organic matter exceeds that of terrestrial oceans by about a factor of 2, and more than a factor of 10 in specific extreme D-rich areas. Such high deuterium excesses trace gas-phase low temperature processes (about 30 K), compatible with the outer regions of the ► [protoplanetary disk](#). The mineral components of UCAMMs mostly consist in fine-grained silicates and Fe-Ni sulfides. The silicates appear as both amorphous and crystalline phases, with individual sizes down to ~50 nm. Among the amorphous phases, some are glassy aggregates containing metal and sulfides (► [GEMS-like](#)) that have been first identified in ► [interplanetary dust particles](#) (IDPs) collected by NASA in the stratosphere. Infrared and Raman analyses of UCAMMs indicate that the abundance of minerals embedded in the organic matter is highly variable, with atomic Si/C ratios of a few percent or lower. The UCAMMs contain both amorphous minerals that may be a direct heritage from the protosolar molecular cloud and crystalline phases that have been processed, in a later stage, within the protoplanetary disk itself. The association of extreme D-rich organic matter with high-temperature minerals confirms that material condensed or processed at close distances from the young Sun can be efficiently transported to several tens of astronomical units, in the outer regions of the protoplanetary disk.

The organic matter of UCAMMs has a polyaromatic structure, as deduced from transmission electron microscopy, IR and Raman spectroscopies. It has a relatively high-bulk nitrogen content compared to the insoluble organic matter (IOM) extracted from carbonaceous chondrites. The atomic N/C ratios of the UCAMM organic matter analyzed so far are ranging from 0.04 up to 0.2. Such values substantially exceed those currently reported in organic matter from primitive meteorites (► [carbonaceous chondrites](#)), chondritic micrometeorites, and most IDPs, which are in the range of 0.01–0.05. The bulk-atomic O/C ratio of organic matter in UCAMMs appears to be

low, a few percent at most. Scanning Transmission X-ray Microscopy coupled with X-ray Absorption Near-Edge Structure (STXM-XANES) showed that the organic matter of UCAMMs is composed of three different phases, two of them bearing resemblance with IOM from meteorites, the third being N-rich (with atomic N/C ratios up to 0.2).

UCAMMs do not have counterpart in meteorite collections. By contrast, UCAMMs bear similarities with a rare type of carbon-rich IDPs, the particles collected by NASA in the comet 26P/Grigg-Skjellerup dust stream, and with the CHON particles observed in comet 1P/Halley by the spatial missions VEGA and GIOTTO. Some rare IDPs exhibit N/C ratios similar to those of UCAMMs in specific sub-micrometer-sized areas, exceptionally as bulk values.

Altogether the chemical, mineralogical, and isotopic data of UCAMMs point toward a cometary origin. However, their extreme organic versus mineral ratio and the high N content of their organic matter require a specific parent body. Incorporating up to several tens of percent of N in the organic matter requires a carbonaceous precursor and energetic processes in an N-dominated environment. Such nitrogen-rich carbonaceous material can be formed by energetic irradiations of nitrogen-rich ices in low-temperature regions of the solar system. Such conditions are encountered at the surface of small objects beyond the trans-Neptunian region, that are submitted to Galactic cosmic ray irradiation.

The UCAMMs provide unique access to the intimate association of high- and low-temperature material from the surface of icy objects, in an unprecedented state of preservation. Therefore, UCAMMs may shed light on physicochemical processes that occurred beyond the nitrogen snow line, revealing organic material from the outer regions of the solar system that cannot be investigated by remote sensing methods.

Acronyms

UC HII region

Definition

It is the dense, ionized gas region surrounding a young, massive star. These regions are smaller and denser than classical HII regions, and they arise at an early stage in the life of a massive star or massive star cluster, after the onset of ultraviolet photon production by the star(s) which ionizes the circumstellar gas but before this over-pressured plasma is able to expand toward pressure equilibrium with the interstellar medium, thus forming a classical HII region.

History

Large-scale radio continuum surveys of the galactic plane, made in the 1960s, identified a number of very compact (unresolved) and bright centimeter-wave radio sources (e.g., Downes and Rinehart 1966). Further observations of these objects with radio interferometers in the 1970s resolved their internal structure, providing accurate measurements of the size and density of these plasma bubbles (e.g., Harris 1973). By the mid-1980s, a dozen or so of these compact HII regions had been identified, with the smallest and densest regions being known as ultracompact HII regions. The situation changed drastically in the late 1980s with the seminal works of Wood and Churchwell (1989a, b). Based on single-dish surveys of compact HII regions, they observed a sample of 80 objects with the Very Large Array and identified 75 ultracompact HII regions. Moreover, correlating their radio survey with the Infrared Astronomical Satellite Point Source Catalog (IRAS PSC), they estimated that as many as 1600 ultracompact HII regions might be present within the galaxy. Subsequent radio surveys have confirmed about half of these and prompted a substantial number of theoretical studies related to this early stage of massive stars.

Overview

Massive stars, i.e., those with a mass greater than about 8 solar masses, produce copious amounts of ultraviolet (UV) photons with energies greater than 13.6 eV, which are able to ionize hydrogen. These stars form within dense molecular cores with typical sizes of about 10^{17} cm and densities of order 10^7 hydrogen molecules per cubic centimeter. Hence, once UV photon emission by the star begins, the circumstellar molecular gas will be dissociated and ionized, forming a plasma bubble, with an initial electron density of order 10^7 cm⁻³ and a temperature of order 10^4 K. The ionized gas is about 100 times hotter than the molecular gas, with a concomitant increase in gas pressure. Hence, the plasma bubble will begin to expand, and the electron density will begin to fall. It is at this stage that the nebula is considered to be an ultracompact HII region, with a size of order 10^{17} – 10^{18} cm and density of order 10^4 cm⁻³.

The size of this photoionized region is determined by equating the rate of ionizing photon emission by the star to the rate of recombinations to excited states of the hydrogen atoms. This analysis was first carried out by B. Strömgren (1939), and the resulting plasma bubbles are known as Strömgren spheres. The hydrodynamic expansion of the Strömgren sphere is highly dependent on the interaction between the ionization front and the shock front, which has been studied quite extensively, both analytically and numerically.

Basic Methodology

Observations of UC HII regions are driven by three key considerations. First, their angular size is small, typically in the range of 0.5–5 arcseconds, and thus high angular resolution is required. Second, their spectral energy distribution peaks in the far infrared, as the stellar radiation is absorbed and reemitted by the dusty envelope of the protostar. Third, the ionized gas, emitting at radio wavelengths, is deeply embedded within dense and dusty molecular cloud cores that present hundreds of magnitudes of extinction

to visible light. This combination of attributes dictates that most observations are made with radio interferometers, operating in the centimeter and millimeter bands. Sub-millimeter and far-infrared observations often lack the angular resolution for studies of the internal structure of the UC HII regions; nevertheless, they can provide important information on the global energetics of the regions and are powerful probes of the molecular cores where the ionized gas is found. The current generation of infrared telescopes allows spectroscopy of less deeply embedded UC HII regions (e.g., Watson and Hanson 1997; Martín-Hernández et al. 2003; Beltrán et al. 2013). Access to this spectral window will be a powerful observational tool for future studies of UC HII regions.

Within the radio window, multifrequency continuum observations provide information on the morphology of the ionized gas and can be used to infer the electron density of the plasma and in turn the rate of ionizing photon emission by the exciting star(s). Radio recombination line observations of highly excited hydrogen atoms provide kinematic information which allow studies of the electron temperature and the internal dynamics of the plasma. Molecular masers, particularly of methanol, water, and hydroxyl, are commonly found in the vicinity of UC HII regions and afford an additional probe of local physical conditions and kinematics.

Theoretical studies of UC HII regions model the expansion process of the nebula and strive to explain the observed morphologies of the regions. Both semi-analytic (e.g., Roth et al. 2014) and numerical studies (e.g., Arthur and Hoare 2006) are common, with the latter using radiation hydrodynamic codes.

Applications

UC HII regions are fairly bright objects at radio wavelengths, and with modern radio telescopes they can be detected throughout the Milky Way, even in regions that are obscured to visible light by dust and interstellar gas. As a result – and in addition to their own intrinsic interest – they are a

useful probe of various galactic properties, including electron temperature, metallicity, and the spatial distribution of massive stars.

Key Research Findings

The most surprising result from Wood and Churchwell’s studies was the large number of UC HII regions. The classical expansion model of a Strömgren sphere, coupled with plausible massive star formation rates, suggests that at any given time we might expect to find at most a few hundred of these objects in the entire galaxy. The much larger number of regions inferred by Wood and Churchwell directly contradicts this expectation, and the discrepancy came to be known as the UC HII “lifetime problem.” Their work suggested that UC HII region lifetimes are several times 10^5 yr – roughly ten times longer than the $\sim 40,000$ yr required to expand beyond the ultracompact state if one assumes the classical expansion model (e.g., Dyson and Williams 1997).

An important consequence of the lifetime problem was the resulting theoretical effort to explain the longevity of these objects. Such efforts generally fall into one of two classes: confinement of the ionized gas by some additional pressure mechanism and replenishment of the (outwardly expanding) ionized gas by the ionization of new neutral material. Fundamental to both of these approaches is the acceptance that the interstellar medium is intrinsically heterogeneous and hence overly simple models (i.e., spherical expansion in a homogeneous isothermal environment) will necessarily miss important physical effects. In particular, the “clumpy” interstellar medium can slow the expansion of the ionized region, serve as a source of raw material to replenish the dense ionized gas, and define the shape (or morphology) of the UC HII region.

A key finding of the early UC HII region surveys was the existence of distinct morphological types. Wood and Churchwell (1989a) identified five morphologies: cometary, core-halo, shell, spherical, and multiply-peaked. A sixth, bipolar morphology has been described by De Pree et al. (2005) and Redman et al. (1998). The

morphology of any given region is determined by many factors, including the age of the region, the density distribution of the circumstellar gas, gas and radiation dynamics, motion of the star, and the presence and strength of a stellar wind, among others. Nevertheless, the fact that only six distinct morphologies have been observed suggests that there is a limited range of physical scenarios that gives rise to these same morphologies. Numerous physical models have been proposed (see review by Churchwell 2002), but observational tests of the models have often been ambiguous. Even so, these attempts to understand the morphologies have proven a rich source of insight into the details of the massive star formation process.

In general terms, the spectral energy distributions of UC HII regions are all the same: at the lowest radio frequencies (~ 1 GHz), the ionized gas is optically thick and presents a rising spectrum, which flattens above a (density-dependent) turnover frequency as the plasma becomes optically thin. Moving into the sub-mm regime, the spectrum rises by two or three orders of magnitude, peaking at wavelengths of a few hundred microns, with the emission arising from the warm dust cocoon surrounding the ionized gas which absorbs most of the stellar luminosity and re-emits it in the mid- and far-infrared. Details of the spectral energy distribution can provide important clues to the structure of the emitting regions. For example, an optically thick spectral index shallower than the nominal (homogeneous) value of +2 is an indication of density gradients within the HII region (Franco et al. 2000). Similarly, the shape of the sub-mm and infrared portions of the spectral energy distribution provides information on the size, location, and composition of the dust and can be used to infer mass accretion rates onto the star (e.g., Wolfire and Churchwell 1994; Osorio et al. 1999).

The electron density-size relation for UC HII regions has been studied by various authors (e.g., Garay and Lizano 1999; Kim and Koo 2001). If the UC HII regions evolve within a homogeneous medium, then one expects the electron density to be proportional to the diameter to the minus three-halves power. However, the exponent is found to be closer to -1 than to -1.5 . The reason(s) for the

shallower relation is not entirely clear. By now it is quite obvious that UC HII regions do *not* evolve in a homogeneous medium, but the smaller value of the exponent can be explained in various ways, both related to the density structure of molecular clouds and to the ionizing photon production of the exciting stars. A definitive understanding of this relation is yet to be established.

Future Directions

Although the lifetime problem is generally considered to be solved, and there is a fairly extensive understanding of the cometary morphology, there are still significant gaps in our knowledge of UC HII regions. The core-halo, multiply-peaked, and bipolar morphologies, in particular, have not been thoroughly investigated. In addition, several recent discoveries related to UC HII regions have yet to be fully explored. These include the presence of extended, lower-density ionized gas surrounding the ultracompact component (e.g., Kurtz et al. 1999; Kim and Koo 2001), the presence of compact radio sources within the ultracompact component (e.g., Rodríguez et al. 2014; Masqué et al. 2017), and the existence of an even smaller and denser class of hypercompact HII regions (e.g., Kurtz 2005; Cesaroni et al. 2019).

Ultramafic Rocks

Daniele L. Pinti

Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Synonyms

[Ultrabasic rocks](#)

Definition

An ultramafic rock is an igneous rock made up to 90% of ferromagnesian silicate minerals (olivine and pyroxene). The Earth's mantle above 400 km depth has an ultramafic composition, comparable to that of a lherzolite, an ultramafic rock of the family of peridotites. The mantle of Mercury may also have a lherzolithic composition (Namur et al. [2016](#)), as that of Mars, though enriched in Na and K compared to the Earth (Kiefer et al. [2015](#)). Komatiite is an ultramafic effusive rock, essentially restricted to the Hadean and Archean age. Reaction of high-temperature hydrothermal fluids with ultramafic rocks at the base of the oceanic crust (Serpentinization) is a process that could have produced abiotically complex organics in the Hadean Earth.

Ultrasmall Bacteria, CPR, and Patescibacteria

Ricardo Amils

Departamento de Biología Molecular, Centro de Biología Molecular Severo Ochoa, Universidad Autónoma de Madrid, Madrid, Spain

Synonyms

[Candidate Phyla Radiation \(CPR\)](#)

Definition

Ultrasmall bacteria, also known as Candidate Phyla Radiation (CPR) and Patescibacteria, is a large group of bacteria which members are mostly uncultivated and only known from genomic reconstruction using metagenomics. A general characteristic of this not well-defined phylum is their small genomes and the lack of important biosynthetic pathways: complete TCA cycles, electron transport complexes, or ATP synthase, which has led to the idea that they are obligate symbionts dependent on fermentation for the generation of cellular energy. Due to their small size ($<0.1 \mu\text{m}^3$), they are not retained in $0.22 \mu\text{m}$ normally used in microbial ecology, so they have been missed until recently in most microbial diversity studies. Their rRNA genes have self-replicating introns and encode proteins, features not usually seen in bacteria. Many of these characteristics are common to the ultrasmall archaea known as DPANN. Their dependence on metabolic symbiotic relationships probably with other

members of the phylum offers an interesting symbiotic hypothesis for the evolution of life systems to a last common ancestor (LUCA).

Palaeobiogeology-Palaeobotany-
Palaeopalynology, Geology Department,
Université de Liège, Quartier Agora, Bâtiment
B18, Liège, Belgium

Definition

The ultrastructure of an object or ► [fossil](#) is its fine structure at the micrometer and nanometer scales.

The term ultrastructure is used to describe the fine structure of a ► [microfossil](#) cell wall, which can be composed of one or several organic layers of various textures and compositions. It is also used in biology of extant organisms to describe the various components of the cell interior, such as nucleus, organelles, internal membranes, and vesicles. The most common technique used to study ultrastructure is transmission electron microscopy.

Ultraviolet Radiation

José Cernicharo Quintanilla
Laboratory of Molecular Astrophysics,
IFF-CSIC, Madrid, Spain

Ultraviolet light (UV) is an electromagnetic radiation with wavelengths between 10 and 400 nm in the domain between X-rays and optical visible light. The UV spectrum is subdivided in different energy domains, from near and medium UV (400–200 nm; 3.10–6.2 eV) to extreme UV, EUV (100–10 nm, 12.4–124 eV). ► [Vacuum ultraviolet](#) light, VUV, corresponds to light having a wavelength between 100 and 200 nm (or 6.2–12.4 eV).

Ulysses Mission

Michel Viso
Innovaxiom, Paris, CX, France

Definition

The joint ESA/NASA Ulysses mission aimed to study the heliosphere as a function of the solar latitude. The spacecraft was launched from the US space shuttle on October 1990. The spin-stabilized spacecraft had a mass of approximately 370 kg at launch. It used the gravitational field of ► [Jupiter](#) (February 8, 1992) to swing out from the ► [ecliptic](#) plane and reach a solar polar orbit of inclination 80.2° at a distance varying from 1.34 to 5.4 AU that it covered in around 6.5 years. The power supply weakening and the ground station becoming unavailable, on June 30, 2009, the agencies stopped the mission after 18 years and 246 days of operations.

Umbriel

Therese Encrenaz
XLESIA, Observatoire de Paris – Section de
Meudon, Meudon, France

Definition

Umbriel is the third of the five big satellites of ► [Uranus](#), in terms of increasing distance to the planet. It orbits at 266,000 km (or ten planetary radii) from Uranus. Its diameter is 1170 km. Voyager 2 images revealed an old cratered surface, where the biggest impact crater, Wunda, is 160 km in diameter. Umbriel does not show any evidence for tectonic activity and appears to be a primitive, undifferentiated body that has remained largely inactive since its formation. Umbriel is the darkest satellite of Uranus, and it has been proposed that its surface could be

covered with a carbonaceous deposit comparable to the dark side of ► [Iapetus](#).

Unidentified Infrared Emission Bands

Sun Kwok
Faculty of Science, The University of Hong
Kong, Hong Kong, China

Definition

The term unidentified infrared emission (UIE) bands refers to a family of emission features observed in a variety of astronomical sources, including the aromatic features at 3.3, 6.2, 7.7, 8.6, and 11.3 μm ; aliphatic features at 3.4 and 6.9 μm ; and broad emission plateaus at 8, 12, and 17 μm , as well as a host of weaker features that are too broad to be atomic or molecular lines.

History

A family of strong infrared emission bands at 3.3, 6.2, 7.7, 8.6, 11.3, and 12.7 μm were first detected in the young carbon-rich planetary nebula NGC 7027 (Gillett et al. 1973; Russell et al. 1977) (Fig. 1) and in the reflection nebula HD 44179 (Russell et al. 1978). Since the initial discovery, these features are now widely observed in ► [HII regions](#), reflection nebulae, planetary nebulae, ► [protoplanetary nebulae](#), and the diffuse ► [interstellar medium](#) of our own and other galaxies.

The UIE feature at 3.3 μm was first identified as the C–H stretching mode of aromatic compounds by Knacke (1977). The chemical origin of the UIE features was discussed by Duley and Williams (1981) who assigned the 3.3 and 11.3 μm features to graphitic (aromatic) materials. Subsequently, Léger and Puget (1984) identified the 6.2 μm feature as due to aromatic C–C stretch,

Unidentified Infrared Emission Bands,

Fig. 1 *Infrared Space Observatory (ISO)* spectrum of the planetary nebula NGC 7027 showing the UIE bands (labeled in red with the wavelength of peak emission in units of microns). Broad emission plateaus around 8 and 12 μm as well as a strong underlying continuum can be seen. The narrow lines (in blue) are atomic lines

the 8.6 μm feature as the C–H in-plane bend, and the 11.3, 12.4, and 13.3 μm features as due to solo, duo, and trio C–H out-of-plane bending modes. Since the UIE bands at 3.3, 6.2, 7.7, 8.6, 11.3, and 12.7 μm almost certainly originate from aromatic materials, they are also sometimes referred to as aromatic infrared bands (AIBs).

Overview

The UIE phenomenon is more than a collection of emission features but is an integrated phenomenon of emission bands, underlying continua, and broad emission plateaus. Also present in astronomical spectra are emission features around 3.4 μm , which arise from symmetric and asymmetric C–H stretching modes of methyl and methylene groups (Puetter et al. 1979; Geballe et al. 1992). The bending modes of these groups also manifest themselves at 6.9 and 7.3 μm (Jourdain de Muizon et al. 1990; Chiar et al. 2000). In addition, there are unidentified emission features at 15.8, 16.4, 17.4, 17.8, and 18.9 μm , which have been observed in protoplanetary nebulae, reflection nebulae, and galaxies.

The emission bands themselves are often accompanied by strong, broad emission plateau

features at 6–9, 10–15, and 15–20 μm . The first two plateau features have been identified as superpositions of in-plane and out-of-plane bending modes emitted by a mixture of aliphatic side groups attached to aromatic rings (Kwok et al. 2001). The 15–20 μm plateau feature has been detected in young stellar objects, compact HII regions, and planetary nebulae, but is especially strong in some protoplanetary nebulae (Zhang et al. 2010). A possible origin of this broad feature arises from C–C–C in-plane and out-of-plane bending of aromatic rings (Van Kerckhoven et al. 2000).

The UIE features are always associated with a strong emission continuum which cannot be explained by free-free emission, reflected starlight, or thermal dust emission heated by stellar photons. For example, scattered starlight is expected to be strongly polarized, but the observed continuum emission is unpolarized. In the diffuse interstellar medium, the strength of the UIE features is strongly correlated with the dust continuum, suggesting that the emission bands are physically related to the continuum (Kahanpää et al. 2003) (Table 1).

The UIE features are seen in very different radiation environments, and their emission peak wavelengths and profiles also vary. The energy

sources responsible for the excitation of the features have temperatures ranging from tens of thousands of degrees in planetary nebulae

(the central star temperature of NGC 7027 is 200,000 K), to $\sim 30,000$ K in HII regions, and to only thousands of degrees in reflection nebulae and protoplanetary nebulae. The UIE features seen in the reflection nebula NGC 7023 are very similar to those seen in the planetary nebula NGC 7027 in spite of the very different intensities of UV background in the two nebulae. Figure 2 shows that the UIE features have very similar profiles, although the central stars of these reflection nebulae have very different temperatures, ranging from 6800 to 19,000 K.

A variety of chemical structures have been suggested as the carriers of the UIE bands. These include ► [polycyclic aromatic hydrocarbon](#) (PAH) molecules (Léger and Puget 1984), small carbonaceous molecules (Bernstein and Lynch 2009), hydrogenated amorphous carbon (HAC), soot and carbon nanoparticles (Hu and Duley 2008), quenched carbonaceous composite (QCC, Sakata et al. 1987) particles, kerogen and coal (Papoular et al. 1989), petroleum fractions (Cataldo et al. 2002), and mixed aromatic/aliphatic organic nanoparticles (MAON, Kwok and Zhang 2011). A complete explanation to the UIE phenomenon has to account for the peak wavelengths and profiles of the emission features, the broad emission plateaus, as well as the underlying continua.

Uraninite

Daniele L. Pinti
Geotop, Research centre for the dynamics of the Earth system, Université du Québec à Montréal, Montréal, QC, Canada

Synonyms

[Uranium dioxide, pitchblende \(former name\)](#)

Chemical Formula (optional)

UO_2

Definition

Uraninite is economically the most important uranium-bearing mineral. The $U^{4+}O_2$ is the reduced form while the oxidized form is triuranium octoxide ($U_3^{4,6+}O_8$ or ideally $UO_2 \cdot 2UO_3$), which occurs in the pitchblende (a mixture of UO_2 and U_3O_8). Uraninite ore deposits are hosted in pegmatites and quartz veins, quartz-pebble conglomerates, and sandstones. Most uraninite-rich ores have ages older than 2.2 Ga. This is taken as evidence of the reduced state of the Archean atmosphere. Indeed, in an oxygenated environment, hexavalent uranium (U^{6+}) is transported in solution as soluble uranyl ($U^{6+}O_2$)²⁺, while in a reduced environment tetravalent uranium (U^{4+}) precipitate to form uraninite $U^{4+}O_2$.

Giant planets

Definition

Orbiting at 19.2 AU from the Sun, Uranus is, after Jupiter and Saturn, the third giant planet by order of size and heliocentric distance. However Uranus, with a mass of 14.5 terrestrial masses, is slightly less massive than the forth giant planet ► [Neptune](#). Uranus is 51,120 km in diameter with a density of 1.27 g/cm^3 . Both Uranus and Neptune consist mostly of an icy core which accounts for more than 50% of their mass, hence their name of “ice giants.” Like all ► [giant planets](#), Uranus has a ring system and several satellites (27 known in 2013). As seen from Earth, the diameter of Uranus is 3.5 arcsec.

Overview

History of Observations

Uranus is the first non-naked-eye planet to be discovered. After several observations by astronomers who mistook the object as a star, Uranus was identified by William Herschel in 1781 using a new-generation telescope. At first, Herschel could not decide whether the object was a comet or a planet; he definitely identified it as a planet in 1783. Still improving his instrument, Herschel detected in 1787 two of the five main Uranian satellites, ► [Titania](#) and ► [Oberon](#), and later the third, ► [Umbriel](#). The satellite ► [Ariel](#) was first detected by William Lassell in 1851 and ► [Miranda](#), the smallest one and closest to the planet, by Gerard Kuiper in 1948.

The orbits of the Uranian satellites gave evidence that the rotation axis of Uranus was tilted in an unusual way. Its angle relative to the north

ecliptic pole is 97.9° , so that the rotation axis of the planet is close to the ► [ecliptic](#) plane. There has been a long debate about the origin of this anomaly. The first possible explanation was that an early collision had tilted the planet, before the collapse of the surrounding gas and the formation of the equatorial disk and the accretion of satellites within this disk. However, recent dynamical calculations show that Uranus’ rotation axis might have been tilted during the planets’ migration, without the need of a major impact, provided that the planet had an additional satellite and a temporary large inclination.

In 1932, R. Wildt discovered methane in the atmosphere of Uranus, as in the other giant planets. Due to its low density, hydrogen was suspected to be a major component of Uranus’ atmosphere, but it was not detected until the 1960s.

Uranus has been explored only by a single spacecraft, Voyager 2, which encountered the planet in 1986. The images returned by the Voyager camera were remarkably devoid of features. The main highlights of the Voyager 2 exploration of Uranus were the first observation of Uranus’ ► [magnetosphere](#), the direct imaging of its ring system, and the discovery of new satellites. Later, Uranus was imaged by the Hubble Space Telescope, which detected more dynamical activity (Fig. 1).

Composition and Structure

Like the other giant planets, the thermal structure of Uranus’ atmosphere is characterized by (1) a troposphere, where the temperature decreases with altitude, following an adiabatic gradient; (2) a tropopause, at a pressure level of about 100 mbar, where the temperature is minimum (about 50 K); and (3) a stratosphere where the temperature increases with the altitude. Due to the cold environment, the atmospheric species found in Uranus are hydrogen, helium, methane, and, in the stratosphere, hydrocarbons produced by the photodissociation of methane (C_2H_2 , C_2H_6). As in other giant planets, oxygen species (H_2O , CO , CO_2) have been found in the stratosphere of Uranus, although in less abundance.

Uranus shows very little atmospheric turbulence. In 1986, Voyager 2 images showed very

Uranus, Fig. 1 Uranus as observed by the Hubble Space Telescope in 2005. A bright cloud appears near the North Pole and a white collar is present in the Southern Hemisphere. (© NASA)

few contrasts. All atmospheric features were symmetric around the rotation axis; there was no evidence for isolated features. Ten years later, images taken with the Hubble Space Telescope (HST) showed a slight evidence of atmospheric activity, possibly correlated with the seasonal evolution. Indeed, cloud features were observed on the disk in 2004, as the planet was approaching ► [equinox](#).

Models of thermochemical equilibrium predict a CH_4 cloud at a level of about 1 bar ($T = 80$ K), an H_2S cloud at about 3 bars, and, at deeper levels of pressure (>20 bars), clouds of NH_4SH and H_2O . However, visible and infrared spectra seem to indicate that the atmosphere of Uranus is relatively cloud free down to a pressure of about

3 bars. Still, methane does condense in the upper troposphere as indicated by its stratospheric abundance, strongly reduced with respect to its tropospheric value.

As in the case of Neptune, the C/H ratio, as measured from the methane abundance below the condensation level of methane, is 20–30 times greater than the protosolar carbon/hydrogen value. This measurement is a strong argument in favor of the nucleation model of the giant planets, which states that their formation began with the accretion of an icy core of about 10–15 terrestrial masses. Another formation diagnostic is the deuterium/hydrogen ratio measured in HD, first detected by the ISO satellite and more recently by Herschel, which indicates, as for Neptune, an enhancement of D/H with respect to the protosolar value; this enhancement is a signature of the presence of a significant icy core. The helium abundance has been measured by Voyager with an uncertainty of about 20%. The inferred He/H ratio shows no difference with respect to its protosolar value (the helium mass fraction Y is 0.275).

Internal Structure

Unlike the other giant planets, Uranus does not exhibit any internal source of energy. The reason for this peculiarity is unknown, but it can probably account for the lack of dynamical activity on Uranus. Models of internal structure predict, at the center, a temperature of about 7000 K and a pressure of about 6 Mbar. As in the case of Neptune, the internal structure of Uranus would consist of a central core of metals and silicates, surrounded by a mixture of ices which would extend up to 0.8 of the planetary radius, covered by a layer of molecular hydrogen. According to this model, there is not supposed to be a layer of metallic hydrogen. As a consequence, in contrast with Jupiter's and Saturn's interiors, helium condensation is not expected to take place; thus, no helium depletion is predicted in the outer atmosphere, which is consistent with the measured helium abundance.

The Magnetosphere of Uranus

The ► [magnetosphere](#) of Uranus has been explored by Voyager 2. As for the other giant

planets, the magnetosphere is well represented by a dipole, but, surprisingly, the axis of the dipole is tilted by 58.6° with respect to the planet's rotation axis; in addition, the dipole shows an offset from the planet's center by a third of the radius. The origin of this anomaly is unknown.

Due to this peculiar geometrical configuration, the magnetosphere of Uranus is very complex. At the time of the Voyager 2 encounter, the rotation axis of Uranus was not far from the Sun-Uranus axis. The magnetosphere looked similar to a terrestrial magnetosphere, which would be in precession around the Sun-Planet axis with the rotation period of Uranus (17.2 h). Strong seasonal variations of the magnetosphere are expected as Uranus moves around its orbit. In 2007, as the planet passed ► [equinox](#), its rotation axis was perpendicular to the Sun-Planet axis and its magnetosphere was then more comparable to the terrestrial one.

Origin and Migration

As mentioned above, Uranus, like the other giant planets, is believed to have formed through the accretion of an icy core of about 10–15 terrestrial masses and the subsequent collapse of the surrounding nebula. According to this scenario, however, it is difficult to form such a massive core at heliocentric distances as high as 20 AU. According to a recent dynamical model developed at Nice Observatory, both Uranus and Neptune would have been formed closer to the Sun but migrated outward following the dissipation of the protoplanetary gaseous disk. This migration mechanism would explain, in particular, the structure of the Kuiper belt and the Late Heavy Bombardment.

Urea

Shin Miyakawa¹ and Didier Despois²

¹Department of Chemistry and Biotechnology, Faculty of Engineering, Yokohama National University, Chiba, Japan

²Laboratoire d'Astrophysique de Bordeaux, Université de Bordeaux, Pessac, France

Synonyms

[Carbamide](#); [Carbonyldiamide](#); NH_2CONH_2

Definition

Urea is an organic compound of molecular formula NH_2CONH_2 . It is an important metabolite (a product of metabolism) formed in the liver of animals through the degradation of three amino acids (arginine, citrulline, and ornithine). It is the main nitrogen-containing substance in the urine of mammals. Urea can be synthesized by spark discharge in simple gas mixtures such as CO , N_2 , and H_2O . Reactions involving urea have been proposed for the formation of the nucleic acid bases Uracil (Subbaraman et al. [1980](#)) and Cytosine (Shapiro [1999](#)). A tentative detection of urea in interstellar ices has been reported.

History

Friedrich Wöhler's synthesis of urea from an inorganic precursor in 1828 was the start of a

revolution in chemistry because it provided the first proof that an “organic” compound could be produced outside a living body. Raunier et al. (2004) proposed a tentative identification of urea in the infrared absorption spectrum of ice mantles of interstellar grains near the protostellar source NGC 7538 IRS9.

Urey's Conception of Origins of Life

Stéphane Tirard

Centre François Viète d'Histoire des Sciences et des Techniques EA 1161, Faculté des Sciences et des Techniques de Nantes, Nantes, France

History

Harold Clayton Urey (1893–1981) was an American physical chemist who earned the Nobel Prize in Chemistry in 1934 for his work on the heavy isotope of hydrogen (deuterium). Urey isolated deuterium by repeatedly distilling a sample of liquid hydrogen and demonstrated the existence of heavy water (HDO). During WWII, Urey contributed to the

Manhattan Project by developing a gaseous diffusion method for separating ²³⁵U from ²³⁸U.

After the war, he moved to academic life where he dedicated to develop cosmochemistry and isotope geology. He firstly speculated that the early terrestrial atmosphere was composed of ammonia, methane, and hydrogen. In 1952, he suggested that experimentation on production of organic compounds from water and methane, in the presence of ultraviolet light or electric discharges, could be most profitable. He insisted on the fact that primitive atmosphere had to be reduced, and for this reason, he criticized Calvin's experiment on origins of life. In 1953, one of his students at the University of Chicago, Stanley Lloyd Miller (1930–2007), produced amino acids under this primitive Earth conditions. This experiment is often named Urey-Miller experiment.

UV Absorption Bump

William M. Irvine

Department of Astronomy, University of Massachusetts, Amherst, MA, USA

Definition

The interstellar extinction curve as measured toward a particular star is normally plotted as

the relative extinction at a given wavelength λ , denoted $E(\lambda - V)/E(B - V)$ vs λ^{-1} , where the quantities E are defined in the entry ► [reddening, interstellar](#). This curve has a “bump” or local extinction maximum at a wavelength of 217.5 ± 1 nm in the ultraviolet, referred to as the UV absorption bump, which is almost invariably detected in the spectra of stars with appreciable reddening. An interesting observational characteristic of the “bump” is that variations in its width as observed along different lines of sight are not accompanied by variations in the wavelength of the maximum absorption. The carrier of this feature is thought to be very small interstellar dust grains, i.e., grains with dimensions ≤ 10 nm. Various carbon-containing substances have been proposed as the grain constituents, including ► [graphite](#), polycyclic aromatic hydrocarbons (PAHs), buckminsterfullerene (C_{60}), and Quenched Carbonaceous Composites (QCCs). This feature has been observed not only in the Milky Way, but also in external galaxies (e.g., Ma et al. [2018](#)).

UV Climate

Gerda Horneck

DLR German Aerospace Center, Institute of Aerospace Medicine, Radiation Biology, Köln, Germany

Keywords

Planetary UV radiation · Terrestrial UV radiation

Definition

The ultraviolet (UV) radiation climate describes the spectrum and intensity of solar UV radiation reaching the surface of a planet as part of the planet's overall climate that encompasses the interplay of various environmental atmospheric factors, such as temperature, radiation, humidity, atmospheric composition, and other elements in a given region over long periods of time.

Overview

The source of the terrestrial ultraviolet (UV) radiation climate is our Sun. At the distance of the Earth the intensity of solar radiation amounts to 1370 W/m^2 , which is called the ► [solar constant](#). This extraterrestrial solar UV spectrum spans over the whole UV range, from 400 nm to short wavelengths extending far into short wavelengths of UVC (100–280 nm) and VUV (100–200 nm) (Table 1).

Solar UV radiation undergoes absorption and scattering as it passes through the Earth's atmosphere. The absorption of solar UV radiation at wavelengths < 290 nm by stratospheric ► [ozone layer](#) is the most important process. As a consequence, the terrestrial UV radiation climate does not encompass energetic ranges at wavelengths < 290 nm (UNEP [1998, 2003](#)).

The ozone concentration in the stratosphere is measured in Dobson units (DU), which

UV Climate, Table 1 Spectral ranges of ultraviolet radiation, as described by the ISO standard (ISO-21348) “Process for determining solar irradiances compliance”

Name	Abbreviation	Wavelength range [nm]	Energy per photon [eV]
Ultraviolet A	UVA	400–315	3.10–3.94
Ultraviolet B	UVB	315–280	3.94–4.43
Ultraviolet C	UVC	280–100	4.43–12.4
Vacuum ultraviolet	VUV	200–100	6.20–12.4
Extreme ultraviolet	EUV	121–10	10.2–124

determines the total amount of ozone present in a vertical column of air above a certain location at the surface of the Earth. It gives the millimeter thickness of ozone at an atmospheric pressure of 1013 hPa and a temperature of 298 K: 1 mm of ozone is equivalent to 100 DU. Near the tropics values reach typically about 260 DU, though there are large seasonal fluctuations. Surface UV radiation levels are highly variable because of sun angle, cloud cover, and also because of local effects including pollutants and surface reflections. A decreasing stratospheric ozone concentration results in higher UV irradiances that may finally stretch into the UVB range of the spectrum. Ozone is photochemically produced from atmospheric oxygen. During the first two billion years of Earth’s history, before the increase of atmospheric oxygen by oxygenic [▶ photosynthesis](#), this effective UV screen by stratospheric ozone was lacking. As a result, the early terrestrial UV climate stretched to the energetic wavelength range up to 200 nm (Cockell and Horneck 2001).

The terrestrial UV radiation climate is beneficial as well as harmful to human health and terrestrial and aquatic ecosystems, depending on dose and wavelength range applied (Horneck 1995; Häder 1997). In biological systems, UV radiation causes temporary or permanent alterations that result from photochemical reactions of UV with different biological target molecules. Beneficial effects are vitamin D synthesis in the skin, harmful effects may lead to diseases of the skin, the eye, and the immune system. The most important UV target in biological systems is the genetic material, the DNA. UV lesions of the DNA may lead to [▶ mutations](#), cancer, and cell death (Hockberger 2002).

The terrestrial UV radiation plays an important role in evolutionary processes, for example, as energy source for chemical evolution on the early Earth and as driver of biological evolution through the generation of mutations. UV-induced mutations may lead to inactivation; however, they may also cause the appearance of new and better adapted attributes of life, such as the origin of efficient [▶ DNA repair mechanisms](#) or the development of sexual processes (Rothschild and Lister 2003).

[UV exposure](#); [UV fluence](#)

Definition

Ultraviolet (UV) radiation is described using radiometric units. They describe the energy that is either emitted from a source or that arrives at a surface. The recommended radiometric SI (International System of Units, abbreviated “SI” from the French *Le Système International d’Unités* as the modern metric system of measurement) derived unit for the flux per unit-area incident on a small plane surface is called “UV irradiance.” It is given in watts/meter² (W/m²). The unit watt (W) is defined as a rate of energy of 1 Joule (J) per second. The UV ► [radiation dose](#), also called “UV exposure” is described in joule/meter² (J/m²), i.e., the energy per unit-area incident on one side of a small plane surface. $1 \text{ J/m}^2 = 1 \text{ W} \times \text{s/m}^2$.

[UV rays](#)

Definition

Ultraviolet (UV) radiation covers the part of the electromagnetic spectrum between the ionizing radiation region and the visible light. Based on the biological effects, it is subdivided into the following bands: UVC (100–280 nm), UVB (280–320 nm), and UVA (320–400 nm). The biological effects that result from UV irradiation are initiated by photochemical absorption by molecules of biological significance. The most important of these are the nucleic acids and to a much lesser extent the proteins and other molecules. If not repaired, the induced photochemical lesions may cause ► [mutations](#), cancer, and cell death.

History

Ultraviolet radiation has been known as a ► [mutagen](#) and disinfectant for more than 100 years. UV from artificial sources, for example, germicidal irradiation, has been used in a variety of applications, such as food, air, and water purification and ► [sterilization](#). In 1903, Niels Finsen was awarded with the Nobel Prize for Medicine “in recognition of his contribution to the treatment of diseases, especially lupus vulgaris, with concentrated light radiation, whereby he has opened a new avenue for medical science.”

Overview

In biological systems, UV radiation causes temporary or permanent alterations that result from photochemical reactions of UV with different biological target molecules. The most important UV target in cells is the genetic material, the ► [DNA](#). The absorbing parts of DNA are the bases, the pyrimidine derivatives thymine and cytosine, and the purine derivatives adenine and guanine. Their absorption spectra dictate the biological sensitivity spectra, the so-called action spectra, which show a maximum in the 260 nm wavelength range (Fig. 1). Adjacent ► [pyrimidine bases](#) are the main DNA targets of direct effects of UVC and UVB radiation. Their excitation leads to the formation of cyclobutane pyrimidine dimers and pyrimidine (6-4) pyrimidone photoproducts (Cadet et al. 2005). In bacterial endospores, due to the structural characteristics of their DNA, UVC induces predominantly 5,6-dihydro-5(α -thyminyl) thymine, the so-called spore photoproduct (Douki et al. 2005). UVA radiation affects the DNA mainly indirectly, mediated by endogenous photosensitizers (Cadet et al. 2009).

During its evolution, life has invented a variety of mechanisms to repair the damage that is induced in its DNA, for example, by UV radiation or other agents. It should be noted that errors occur very often in the DNA during its replication. Therefore, there exists a whole set of mechanisms

UV Radiation, Biological Effects, Fig. 1 Action spectra for different biological effects of UV radiation

to control the integrity of the DNA and to initiate its repair if necessary. Each of these repair mechanisms is catalyzed by a different set of enzymes.

The main ► **DNA repair** processes can be divided in:

- Direct repair pathways, where the abnormality in the DNA is reversed in situ; an example is the photoreactivation of UV radiation damage, where the photoproduct, the cyclobutane thymine dimer, is enzymatically split under the activation of visible light.
- Excision repair pathways, where the section of the DNA containing the abnormality is excised from the strand and repair patch is synthesized using the intact sister strand as template.
- Recombination repair, where the abnormality is repaired by homologous recombination with a second DNA strand.
- SOS repair, which is an inducible repair process that is initiated after the DNA has been severely damaged; this is a highly error-prone repair leading to a high frequency of mutations.

Some of these repair pathways are very old and have been preserved in the different domains of

life. Photoreactivation is a very universal process, which is found in representatives of all three domains of life, in Bacteria, Archaea, and Eukarya. Other repair pathways, for example, the nucleotide excision repair, have a separate origin in prokaryotes and eukaryotes (Friedberg 1995, 2008). If not or inaccurately repaired, the UV-induced DNA photoproducts may lead to mutations and finally to cell death.

Solar UV radiation was an important energy source for chemical evolution on the early Earth, long before life arose. Since the appearance of life on Earth, solar UV radiation has provided an evolutionary challenge. On the one hand, because of its damaging nature to the genome, UV radiation has acted as a selective agent. On the other hand, UV-induced mutations may have had all sorts of evolutionary consequences, ranging from the development of efficient DNA repair pathways to sexual processes (Rothschild and Lister 2003).

Valine

Kensei Kobayashi
Yokohama National University, Yokohama, Japan

Definition

Valine is one of the 20 ▶ [protein](#) amino acids. Its chemical structure is $(\text{CH}_3)_2\text{CHCH}(\text{NH}_2)\text{COOH}$. Its three-letter symbol is Val, and its one-letter

symbol is V. Its molecular formula is $C_5H_{11}NO_2$ which translates into a molecular weight of 117.15. Its isoelectric point is 5.96. Valine's side chain is a simple hydrocarbon and is thus considered to be an apolar amino acid. Among the protein amino acids, alanine ($C_3H_7NO_2$), leucine, and isoleucine (both $C_6H_{13}NO_2$) are in the same group, but strangely, none of the isomers with four carbons ($C_4H_9NO_2$) are protein amino acids. Valine has 11 nonprotein ► [amino acid](#) isomers, including norvaline and ► [isovaline](#). All of them have been identified in the extract from ► [Murchison meteorite](#). Valine is a hydrophobic amino acid and has often been used to make thermal microspheres from amino acids.

Synonyms

[Molecular interactions](#)

Overview

The interactions between electrons and nuclei, whether they are or not part of the same molecule, are electromagnetic. This means that, at least in principle, the same theoretical tool, quantum

mechanics, can be used to calculate the interaction energies between bonded atoms or nonbonded atoms. At the intramolecular level, various methods can be used to calculate these energies, from truly theoretical *ab initio* methods to semiempirical methods like the “old” Hückel method or the “modern” Density Functional Theory (DFT) method. As soon as the number of nuclei and electrons increases, *ab initio* calculations become too time-consuming and semiempirical methods are preferred. In the case of intermolecular interactions, except in the case of pair interactions between small molecules like water or methane, the interaction energies are furthermore generally calculated using classical methods, and the van der Waals approach, named after the Dutch scientist Johannes Diderik van der Waals (1837–1923), is frequently used. The basis of this approach is very simple: the interacting molecules are described as ensembles of electric charges (positive for the nuclei, negative for the electrons). The ensemble of charges is neutral except if the molecules are charged (ions). As soon as the distance between the charges inside each molecule is much smaller than the distances between the molecules, it is possible to approximate the charge distribution of each molecule by a series of electric multipolar moments (multipolar expansion). The condition concerning the distances between the electric charges is of course better fulfilled in the gas phase than in the liquid phase, and this explains why the use of the multipolar expansion gives, at best, only a rough estimation of the intermolecular interaction energies in the liquid phase.

The first nonzero multipolar moment of a molecule is the monopole in the case of ions. In the case of neutral molecules, it can be the dipole moment, as in the case of water or HCl molecules. It is the quadrupolar moment in the case of methane or benzene, and for highly symmetrical (octahedral) molecules, like SF₆, the first nonzero moment is the octupolar moment. The only molecules, which are truly apolar, are the monoatomic rare gases. Frequently, the multipolar expansion is truncated to the dipole term, which means that the electrostatic interaction energies between neutral molecules are often described as dipole-dipole

interactions, called Keesom interaction energies. For molecules able to reorient themselves, the Keesom term is always negative and is a function of r^{-6} , where r is the average intermolecular distance, i.e., the distance between the centers of mass of the interacting molecules. The truncation of the multipolar expansion to the dipolar term can be misleading in the case of molecules, which do not possess a dipole moment and which are consequently considered “apolar.” For example, the “T-shape” geometry of the benzene dimer observed in the gas phase is easily explained by taking the (quadru)polarity of benzene into account.

Any molecular charge distribution immersed in an electric field is polarized as the distribution is slightly modified by the electric field. Consequently, a molecule immersed in the electric field created by another polar molecule acquires induced moments. For example, an apolar xenon atom acquires a small dipole moment in the vicinity of a dipolar molecule. A multipole-induced multipole interaction energy must therefore be taken into account in the estimation of intermolecular interaction energies. This contribution to the intermolecular interaction is called, in the case of a dipole-induced dipole interaction, the Debye term. It is always negative and is also a function of r^{-6} . It is smaller in absolute value than the Keesom term.

The Keesom and Debye terms can however not explain why, for example, monoatomic rare gases can be liquefied or why the transition from the liquid to the gas phase requires energy (heat of vaporization). The favorable (negative) interaction energy at the origin of these phenomena is ubiquitous: it exists between xenon atoms but also between water molecules. Furthermore, except in the case of molecules with a large dipole moment (like water molecules), this interaction energy term, which is named the London term, is always larger in absolute value than the Keesom term. It is not possible to give an explanation of the origin of the London interaction energies using classical physics; quantum physics is required. At best, it is possible to give a crude model by saying that a charge distribution is always fluctuating. In the case of a monoatomic species, which can be

described as a spherical distribution of electrons around a positive nucleus, a fluctuating distribution means that the instantaneous electronic distribution can be nonspherical leading to the formation of an instantaneous dipole. Any instantaneous dipole is itself able to induce an instantaneous induced dipole in a charge distribution in its vicinity. These instantaneous dipoles can be very large, and this is the reason why the London contributions to the intermolecular interaction energies are generally the largest of all the energies responsible for the cohesion of liquids and solids. As in the case of the Keesom and Debye terms, the distance dependence is a r^{-6} law.

The three abovementioned terms are negative and cannot explain why matter is not infinitely compressible. A repulsive force, a positive energy contribution, must necessarily also be present. The origin of this contribution cannot be explained on the basis of classical physics; it is related to the Pauli principle, which implies that it is impossible to place more than two electrons in the same orbital. The distance dependence of the Pauli positive interaction energy is frequently given by a r^{-12} law; however, other laws are also used.

What is often called the van der Waals interaction includes the Keesom, Debye, London, and Pauli contributions and represents the electrostatic interaction between nonbonded atoms other than the ionic interaction. Some authors, however, only use the term for the attractive contributions, and some even use it solely as a synonym for the London dispersion forces.

The intermolecular potential between monoatomic species, which can interact only through the attractive London force and repulsive Pauli force (the isotropic terms), is frequently approximated by an empirical law of the type

$$E = -A/r^6 + B/r^{12}$$

where A and B are constants depending on the nature of the interacting atoms. The potential with this type of analytical form is called a Lennard-Jones potential. A law of this kind is characterized by a minimum, and the r value of this minimum corresponds to the sum of the van

der Waals radii of the two interacting species. It can be used to describe interactions between nonbonded atoms, these atoms being in the same molecule (intramolecular interactions) or in different molecules (intermolecular interactions), and tables give the so-called van der Waals radii of all atoms. In molecular models, when atoms are represented by spheres of various sizes (and colors), the radii of these spheres are generally (but not always) proportional to the van de Waals radii of the corresponding atoms.

Variability, Stellar

Daniel Rouan

LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

Variability characterizes the changes over time of the apparent brightness of a star. Stars may exhibit long-term variations of their intrinsic luminosity, as the Sun, for instance, whose luminosity changes by about 0.1% over an 11-year solar cycle. Active stars with numerous spots present a large variability. Stars can also show a periodic variation on a shorter time scale of minutes (oscillations) to years (pulsations). The change can be dramatic as in cataclysmic variables or

extremely subtle when it's a mere oscillation. Finally, stars may also suffer partial eclipses from an orbiting companion (another star or planet). Variability is typically measured in mmag (milli-► [magnitudes](#)).

Definition

Vega 1 and Vega 2 (contraction of Venus and Halley in Russian) were two identical spacecraft designed by the USSR in cooperation with European countries to investigate ► [Venus](#) and ► [Comet Halley](#). Launched from Baikonur by Proton rockets, respectively, on 15 and 21 December 1984, they released modules into Venus's atmosphere and then flew through Halley's coma on 6 and 9 March 1986, at 8900 and 8000 km nucleocentric distance. The television system (TVS) provided, after noise cleaning, the first evidence for the existence of a cometary nucleus. The dust mass spectrometers (PUMA) allowed a major discovery to be made. It indeed detected the presence of a large amount of organic molecules within cometary dust particles, so-called CHON, where this acronym stands for the most abundant elements: carbon, hydrogen, oxygen, and nitrogen.

The close flyby of the nucleus of comet Halley on 13 March 1986 by the ESA (European Space Agency) Giotto mission was made possible by the navigation data of the two Vega spacecraft. They were indeed playing the role of pathfinders for Giotto, which could flyby Halley nucleus at a distance of only 600 km.

Definition

Venus is the second ► [terrestrial planet](#) from the Sun. It is in many of its key parameters very similar to ► [Earth](#). The planet, however, has a thick CO₂ atmosphere with a ground pressure of 95 bar (compared to 1 bar for the Earth) and sulfuric acid clouds that permanently shroud the planetary surface. The atmosphere induces a strong ► [greenhouse effect](#) with surface temperature of more than 500 °C. Surface landforms are dominated by volcanic and tectonic activities. Based on the random distribution of craters, the global surface seems to be young, with an average age of 500 million to 1 billion years.

History

Galileo's observations of the phases of Venus provided crucial evidence for Copernicus' heliocentric theory of the solar system. Mikhail Lomonosov discovered the atmosphere of Venus during its 1761 transit of the Sun (cf. M. Marov, *Transits of Venus: New Views of the Solar System and Galaxy*, Proceedings of IAU Colloquium #196). The high surface temperature was first measured by radio astronomers in the 1950s, while the rotation period and obliquity were determined by ground-based radar in the 1960s. The nature of the clouds as sulfuric acid droplets was deduced from observations of the polarization of reflected sunlight as a function of wavelength and phase angle (the angle Sun-planet-Earth) by Hansen and Hovenier (1974).

Basic Methodology

Most of what we know about Venus is based on spacecraft exploration:

- First flyby by NASA spacecraft: Mariner 2 (1962) and Mariner 5 (1967).
- After several attempts, several Soviet probes were able to descend through the atmosphere (Venera 4, 1967; Venera 5 and 6 in 1969) and

land successfully, starting with Venera 7 (1970) and Venera 8 (1972). The increasingly sophisticated landers Venera 9–14 (1975–1981) and Vega 2 (1986) were able to transmit images and analyses from the surface.

- NASA sent a major exploration mission, “Pioneer Venus,” composed of one orbiter and four atmospheric probes in 1978.
- The detailed surface, previously hidden by the clouds, was revealed by the Soviet missions, Venera 15 and 16 (1983), and especially by the NASA orbiter Magellan (1989) which mapped the planet with a 100–200-m resolution.
- The Vega 1 and 2 missions put two balloons in the atmosphere in 1986. They flew for 2 Earth days, covering almost 12,000 km around the planet.
- Since April 2006, the European Space Agency orbiter Venus Express has resumed the monitoring of Venus, focusing on the atmosphere and the climate of Venus and mapping the surface for the first time in the near-infrared spectral range.
- The Japanese space agency JAXA launched the Venus Climate Orbiter (“Akatsuki”) in May 2010. Unfortunately, the probe failed its insertion into Venus orbit on December 7, 2010.

Key Research Findings

Key Characteristics

Venus is the nearest planet to the Earth, both in terms of distance and in overall size and mass (Table 1).

The rotational axis of Venus is nearly perpendicular to the ecliptic, and the orbit is nearly circular, so seasonal changes in the climate are probably very small. The Venusian year is 224.7 Earth days, longer than the time for Venus to rotate on its axis, which is 243 Earth days. The solar day, defined as the time for the Sun to go from noon to noon as seen from the surface of Venus, is about 117 Earth days. This very slow rotation of the solid body of Venus is retrograde, that is, backward, compared to the other planets.

Venus, Table 1 Basic data for Venus and the ratio to the value of the same parameter for the Earth

	Venus	Venus/ Earth
Mass	4.87×10^{24} kg	0.815
Radius	6051 km	0.95
Density	5.2 kg/m^3	0.943
Equatorial gravity	8.87 m s^{-2}	0.907
Rotation period	243 Earth days (retrograde)	243
Orbital period	224.7 Earth days	0.615
Obliquity	2.7°	0.115
Orbital eccentricity	0.007	0.407
Mean distance from the Sun	108.2×10^6 km	0.723

Surface Geology

The surface of Venus is dominated by tectonic and volcanic landforms. Radar images and altimetry data show that a mosaic of volcanic plains covers about 80% of the surface. Among the plains stand several continent-sized upland plateaus made of intensely deformed “tessera” terrain and broad topographic rises with associated volcanoes and converging rifts (Basilevsky and Head 2002).

Plains

The most abundant unit among the plains is the so-called regional plains, which occupy 65–70% of the surface and are represented by two major varieties:

- The *wrinkle ridge plains* have a rather smooth surface, often with flow-like features most likely made of solidified lava flows. These plains are deformed with a network of relatively narrow wrinkle ridges, which are the result of moderate horizontal compression. Large areas occupied by the flow-like features and very gentle slopes, along which the material flowed, indicate high-yield eruptions of liquid, nonviscous, probably basaltic lava which formed plains, subsequently deformed by wrinkle ridges. The suggestion of basaltic composition of the lava is supported by the analysis of the Magellan images for the location of the Venera/Vega landers.

- The *shield plains* are less abundant and usually form fields of a few hundred kilometers across. Their surface is peppered with gentle-sloping volcanic shields 5–15 km in diameter. Coalescing flanks of the shields form most of the plains' surface. The gentle slopes of the shields imply that they are made of nonviscous, probably basaltic lava. However, the differences in morphologies of the shield plains and plains with wrinkle ridges could be due to compositional differences of the composing lavas.

About 10–15% of Venus' surface is occupied by younger volcanic units, which are obviously superposed on regional plains and are not deformed by wrinkle ridges. Many of them consist of numerous volcanic flows with lobate morphology. The large length of the flows on gentle to almost horizontal surfaces implies low viscosity of the lava. This, in turn, is usually considered as evidence of basaltic composition (Basilevsky and Head 2002).

Among the regional plains, more often in association with the shield plains, are observed steep-sloped volcanic domes of a few to several tens of kilometers in diameter. The high steepness of their slopes is believed to be due to high viscosity of the composing lavas. One of the possible explanations of this high viscosity is that the lava is geochemically evolved, with a rather siliceous composition. However, the high viscosity of the dome-forming materials could also be the result of the presence of gas. The high atmospheric pressure on Venus' surface is not favorable for the near-surface degassing of ► [magma](#), so lavas on the surface may be saturated with gas bubbles and thus be viscous, even if their chemistry is rather usual (Head et al. 1992).

About 20% of the surface of Venus is occupied by terrains that are topographically rough due to tectonic deformation. These are the so-called ridge belts, densely fractured plains, tesserae, and the mountain belts surrounding plateau Lakshmi, as well as rift zones. The regional plains embay and partly bury almost all of them except the majority of rifts.

Ridge belts form a global-wide system, which is now seen only in fragments standing high

enough not to be flooded by lava from the surrounding regional plains, which in most observed cases embay the belts. The ridge belts are composed of plains-forming material looking very similar to that of the plains with wrinkle ridges. It is probably also a solidified basaltic lava folded into relatively broad ridges arranged into parallel bands.

Plateau, "Tesserae," and Mountains

Tesserae form "islands" and "continents" standing above the surrounding regional plains, which obviously embay the tessera (Fig. 2). When tesserae are in contact with ridge belts and densely fractured plains, it is seen that materials composing these two units embay tessera terrain. The surfaces of tesserae are very rough, being dissected by numerous crisscrossing ridges and grooves a few kilometers wide and tens of kilometers long. The ridges are evidently formed by compressional tectonic deformation, while many grooves are extensional structures. The surface of tessera terrain looks bright on the Magellan images. This is due to high roughness on meter to decameter scales, also resulting from the tectonic deformation. The compositional nature of tessera terrain material is unknown. Some researchers suggest that it has a basaltic composition. Others believe that tessera may be made of more feldspathic material resembling to some degree the anorthosites of the Moon or granites of the Earth. A recent analysis of data from the VIRTIS instrument on the ESA mission Venus Express, providing images at the wavelength of the atmospheric window at 1.02 μm , shows evidence for variation of surface emissivity on the Southern Hemisphere (Mueller et al. 2008). The inferred surface emissivity is correlated to some extent with morphological units identified from radar images of the NASA/JPL Magellan mission. Alpha and Phoebe Regios are highlands mostly composed of tessera terrain. In comparison to lowland plains and other less-tectonized highlands, these regions generally emit less thermal radiation, which implies lower emissivity. An analysis of near-infrared wavelength data from the Galileo flyby in 1990 also finds that highland regions on Venus on average have a lower

emissivity than lowlands (Hashimoto and Sugita 2003). As a significant part of the Venus highlands in the area observed by Galileo is composed of tessera, this observation is consistent with the more global observation of VIRTIS on Venus Express (Mueller et al. 2008).

Mountain ranges surrounding the volcanic plateau Lakshmi form a specific terrain type. They consist of clusters of parallel (within the given range) ridges resembling the ridge belts described above on plains. But mountain ranges differ from the ridge belts in that their heights are very large. The summit of the highest of them, Maxwell Montes, stands more than 11 km above the mean planetary radius. Parallel ridging and high altitudes of the mountain ranges imply that they formed due to intense horizontal compression. As in the case of tessera terrain, the composition of the mountain range material is unknown.

The top parts of the mountain ranges (and of some other highlands of Venus as well) have extremely high radar reflectivity and look very bright on the Magellan radar images. This brightening appears above some critical altitude (somewhat changing from place to place), which is often referred to as the “snow line.” The chemical composition of the lower atmosphere (in particular the CO/CO₂ and COS mixing ratios) is crucial to understanding the effects of chemical weathering on the surface of Venus. In this process, the iron in silicates, such as pyroxenes and olivines, was believed to segregate into minerals having a high electric conductivity (iron oxides or sulfides). These minerals very efficiently reflect the radio waves, making the surface very radar bright. The mineral responsible for the radar anomalies on mountain tops and volcano edifices appears to be the electrical semiconductor pyrite, whereas ► [magnetite](#) is thought to characterize the regions of lower altitude. Other researchers suggested that the high reflectivity is due to surface films of some metals vaporized from the rocks at the lower hotter places and deposited on the cooler mountain tops. Interestingly, Maat Mons volcano, which reaches ~6000 m of height, does not show this low emissivity at the summit. This has been interpreted as possible evidence for

recent volcanic activity, which prevented the weathering effect at high altitude.

Rifts

Venusian rifts are rather similar to continental rifts on Earth and form a global system up to 40,000-km long. They are typically troughs, whose floor may be several kilometers below the neighboring non-rifted terrain, while the rims of the troughs are often uplifted above the neighboring terrain. The walls and floors of the troughs are fractured, often very heavily. Young post-regional-plains lava fields and volcanic constructs are frequently associated with rifts. The general consensus is that rifts formed in the environment of tectonic extension. Rifts of Venus cut not only post-regional-plains units but all other geologic units of this planet as well. Most of the observed rifts are younger than the regional plains, but some are older (designated by some researchers as fracture belts) and seen as fragments partly flooded by the lavas of regional plains.

Coronae

Several hundred specific volcanic-tectonic structures called “coronae” (“corona” singular) are observed on the surface of Venus. Coronae are oval to circular features typically of 100–300 km in diameter. A few of the coronae are even larger. They have a circular or nearly circular, tectonically deformed annulus, which usually stands a few hundred meters above the surrounding plains. The area inside the annulus is typically lower than the surrounding plains and flooded with plains-forming volcanics. Aprons of young lobate volcanic flows are seen radiating from many coronae. At the center of some coronae, an elevated and tectonically deformed area, the corona core, is seen. Coronae are considered to form as a result of the rising of hot material in the ► [mantle](#). The potential compositional similarity or difference of coronae with other landforms and terrains makes the largest of them a target for study with the Venus Express instruments (Helbert et al. 2008).

Impact Craters and Surface Age

The thick atmosphere of Venus effectively screens the surface from impacts of smaller bodies. Typically, objects with a diameter smaller than 30 m

should not make it to the surface with enough of their initial velocity to produce a crater. Radar imaging of the surface shows more than 960 impact craters from 1.5 to 270 km in diameter. Of this, only a very small percentage of impact craters are smaller than 30 km, confirming the atmospheric screening effect. Surprisingly, the distribution of these approximately 1000 craters on Venus seems undistinguishable from (or very close to) a random scattering. Unlike on ► [Mars](#) or ► [Mercury](#), no heavily cratered older terrains are found on Venus. All craters on Venus appear to be very pristine, indicating that erosion plays no important role on Venus, in contrast to Earth where craters are effectively removed by erosion and resurfacing. Exogenic resurfacing on Venus is essentially dominated by eolian processes. The observed eolian features are represented by radar-dark mantles, wind streaks, yardangs, and dunes.

The crater size and density distribution as a proxy for the surface age (see chronology) indicates that the surface was globally formed between 500 million and 1 billion years ago. There are two competing theories to explain this apparently young surface age. The so-called equilibrium theory assumes volcanic activity destroys craters at approximately the same rate as new craters are formed. Therefore, always the same number of craters is observed on the surface of Venus. This would imply a constant volcanic activity over large parts or even the whole geological history of Venus. The competing so-called catastrophic theory assumes that a catastrophic resurfacing event approximately 500 million years ago reformed the whole surface of the ► [planet](#) in a very short time period. All craters and the entire earlier geological record were erased in this resurfacing event. After this event, only faulting and localized volcanic activity has further altered the surface. Between these two end-member theories, any combination of these two is possible. Without actual dating of surface samples at various locations, it seems impossible to obtain a final answer. Recent results from Venus Express indicate that hot spot volcanism in localized areas has been ongoing on Venus in the very recent geological history (Smrekar et al. [2010](#)).

Venus Crust and Mantle Dynamics

Venus and Earth lose heat in very different ways (compare heat transfer). ► [Plate tectonics](#) on Earth leads to a recycling of the ► [crust](#) through plate growth, motion, and subduction. For Venus, there is no indication for plate tectonics on a global scale at all. At the same time, widespread volcanism and tectonic deformation are observed. This might indicate that Venus volcanism triggered by mantle upwellings may contribute to the heat loss from the interior while the tectonic deformation may be indicative of and caused by mantle downwelling.

In situ measurements by the Venera and Vega landers are at most places consistent with a basaltic surface composition. The hypsometric curve of Venus is unimodal. As discussed above, the inferred lava viscosity of most volcanic features is low, consistent with basaltic composition. All these observations point toward a crust mostly composed of ► [basalt](#). However, no landing site was on tessera terrain, tesserae are elevated, and the morphology is dominated by tectonic deformation. As stated before, these considerations lead to the hypothesis that tessera highland crust is more abundant in feldspar and silica, relative to lunar highlands or continents on Earth. Recent near-infrared mapping supports this hypothesis, although other interpretations of the near-infrared data cannot be ruled out.

Generation of felsic crust is unlikely under the current climatic and tectonic regime on Venus. The lunar highland crust is believed to be a remnant of a magma ocean. Enrichment in silica as in the ► [continental crust](#) of Earth requires recycling of water into the mantle. The surface of Venus is extremely dry and crustal recycling by plate tectonics does not operate at present. Any crust with felsic bulk composition would have had to be created during the early history of the planet. From a stratigraphic analysis, tessera terrain predates all units it is in contact with (Ivanov and Head [1996](#)). Tessera terrain is characterized defined by an extensive history of tectonic deformation. Assuming that tessera highlands indeed represent less-dense crustal blocks created early in the history of Venus, implications arise from their persistence on the surface of Venus regarding

Venus, Fig. 1 A hemispheric view of Venus centered at 180° east longitude. The 3-km surface roughness is shaded (with illumination from the west) and is color-coded to represent elevation. The image is mostly based on Magellan images, complemented by Earth-based radar data as well as Venera and Pioneer Venus altimetry

resurfacing mechanism, crustal recycling, and thermal evolution. If tessera highlands are enriched in silica relative to basalt, this implies existence of a primordial ocean on Venus. In either case, Venus would even more closely resemble the Earth than previously assumed, making Venus an excellent subject for general studies of earthlike planets (Figs. 1 and 2).

Venus Atmosphere and Climate

Present Atmospheric Composition

The massive Venus atmosphere (about 90 bar) is primarily composed of ► carbon dioxide (96%) and a few percent of inert gases (nitrogen, argon). The relatively high abundance of sulfur dioxide in Venus’ clouds is suggestive of extensive volcanic activity. This sulfur dioxide combines with liquid water to make thick H₂SO₄-H₂O ► clouds (Table 2).

Thermal Structure and Greenhouse Effect

Venus is closer to the Sun than the Earth and receives about twice the incidence of solar energy. However, the highly reflective cloud cover on

Venus, Fig. 2 A radar image of a Venus “tessera”: Alpha Regio is a roughly square region of tessera about 1500 km across and centered at 22°S, 5°E. The surrounding volcanic plains appear to have flowed around Alpha’s margins and thus are younger than Alpha

Venus, Table 2 Composition of the Venus and Earth atmospheres as fractional abundances (volume mixing ratio) except where ppm (parts per million) is stated

	Venus	Earth
Carbon dioxide	0.96	0.0003
Nitrogen	0.035	0.770
Argon	0.00007	0.0093
Water vapor	~0.0001(?)	~0.01
Oxygen	0.0013	0.21
Sulfur dioxide	0.00015	0.2 ppb
Carbon monoxide	0.00004	0.12 ppm
Neon	5 ppm	18 ppm

Venus reflects 76% of the incoming solar flux and which results in a *smaller* net ► solar constant for Venus than for Earth. An airless body with the same ► albedo and at the same distance from the Sun as Venus would reach equilibrium at a temperature below –40 K.

Therefore, the high surface temperature primarily results from a 500 °C greenhouse warming produced by the thick, cloudy atmosphere. The details of Venus greenhouse effect are not easy to quantify, however. The massive amounts of carbon dioxide are very effective at blocking the emission of thermal infrared radiation, but only at those wavelengths where the gas has absorption bands, which are far from covering the entire

spectrum. Moderate amounts of water vapor are also required, and even then considerable spectral gaps or “windows” remain. These are thought to be blocked by the clouds made of sulfuric acid droplets. These have the property of being highly absorbing at thermal infrared wavelengths, while being nearly conservative (non-absorbing) scatterers in the visible and near infrared. Thus, the clouds tend to diffuse downward those of the incoming solar photons that they do not reflect to space, while blocking thermal emission from the lower atmosphere and surface. Overall, radiative transfer models, involving weak as well as strong bands of CO₂ and H₂O, plus those of the minor constituents CO, HCl, and SO₂, can account for the high surface temperatures by careful incorporation of the scattering and absorbing properties of the clouds.

Figure 3 shows the mean Venus temperature profile. The solar radiation that penetrates the clouds warms the lower atmosphere, which is prevented by the ► [opacity](#) of the overlying layers from cooling by radiation (see heat transfer) to space. It therefore forms a deep convective region, the troposphere. This links the high surface temperature of around 730 K with the level at which the temperature is close to the effective bolometric temperature of Venus (about 230 K), where strong radiative cooling to space can occur.

Above the troposphere and the clouds’ top, between 60 to about 100 km, the temperature can remain close to the adiabatic lapse rate, that

is, it is largely convectively driven. However, in the upper part of this lower mesosphere region, the temperature tends to become constant with height as the atmosphere becomes optically thinner, and, to a first approximation, each layer tends to find a radiative equilibrium temperature. On the Earth, this situation is altered by the ► [ozone layer](#), which is responsible for substantial heating in the stratosphere and the mesosphere. There is no corresponding effect on Venus, except for small amounts of absorption of solar and thermal energy in the near-infrared bands of water vapor and carbon dioxide. This absorption produces a mesopeak (or local temperature maximum) in global radiative equilibrium models around 110 km. The thermosphere is reached at heights of more than 120 km above the surface. Here, the atmosphere is very rarified, and short-wavelength solar radiation and energetic particles drive rapid photochemical reactions and produce high temperatures by day. At night, when the heating is absent, efficient radiative cooling by CO₂ results in a rapid decline of temperature, so there is a sharp gradient across the terminator, from over 300 K on the illuminated hemisphere down to 100 K or less on the nightside.

Atmospheric Circulation

The atmospheric circulation is characterized by a super-rotation of the atmosphere; that is, at almost all latitudes, near the cloud top, the wind is prograde and the wind speed larger than 100 m/s. The

Venus, Fig. 3 Vertical structure of the Venus atmosphere based on the Venus International Reference Atmosphere (VIRA)

clouds thus seem to rotate in about 4–5 Earth days, much faster than the surface. Below the clouds (about 60 km), the four Pioneer Venus and many Venera entry probes have shown that the winds fall gradually in velocity as the atmosphere becomes denser. The super-rotation of the Venus atmosphere remains a scientific puzzle. The mechanism that maintains this super-rotation should involve transport of angular momentum by the Hadley circulation and by planetary atmospheric waves. However, key aspects of the three-dimensional structure of the global circulation on Venus have not yet been measured. A key question is the role of the waves induced by the diurnal cycle (thermal tides).

Above the cloud tops (80–140 km), the Venus atmosphere shows two flow regimes – (1) a stable subsolar to antisolar point circulation driven by solar near infrared and extreme ultraviolet heating and (2) a super-rotating zonal flow that varies greatly over time. Breaking gravity waves

propagating from below have been observed and appear to dissipate in the 140–150-km region.

Near the poles on Venus, a complex, a polar collar takes the form of a ribbon of very cold air, some 10-km deep and a thousand kilometer in radius, centered on the pole. Inside the collar, temperatures are some 40 K cooler than outside the feature. Poleward of the inner edge of the collar lies a polar “dipole” consisting of a pair of wide coupled vortices circulating around the pole. The dynamics of this structure is active and complex. It can even sometime become a tripole (Fig. 4).

Clouds and Photochemistry

Venus is completely enshrouded by clouds in a complex layered structure over 30-km deep, between altitudes of 45 km and about 75 km (in some locations, a thin haze may extend down to 30 km). Sulfuric acid particles with radii around 1–10 μm are thought to dominate the composition

Venus, Fig. 4 Venus observed by Venus Express (VMC camera). These images obtained in the ultraviolet (UV) illustrate the complex atmospheric dynamics and the cloud variability near the pole. Images (a–c) are separated by less than 24 h in June 2006. Figure (d) was obtained on January 13, 2007. (Credits: ESA)

of the clouds of Venus. They are generated photochemically from SO_2 and OCS in the upper Venus atmosphere. However, the photochemical processes likely also involve chlorine, which has long been detected in the Venus atmosphere. Active photochemical processes not unlike those observed in the Earth's stratosphere have been postulated to occur on Venus (DeMore and Yung 1982). They must also stabilize Venus' atmosphere, where various catalytic cycles or heterogeneous processes convert the photodissociated products of CO_2 , CO , and O_2 , back to CO_2 .

Structure can be seen in the clouds if they are observed in reflected sunlight through an ultraviolet filter, due to the presence of an absorber mixed with the sulfuric acid droplet. The nature of the UV absorber is still unclear. Monitoring of the UV contrasts through imaging from Venus Express has shown a dynamic behavior that has been suggestive of convective connections in equatorial latitudes (Titov et al. 2008).

The lower cloud region is less well known. It is also likely to be composed primarily of sulfuric acid droplets. X-ray fluorescence data from the Soviet Vega descent probes also found significant and spatially variable quantities of Cl, P, and Fe in the lower cloud particles, although it is not clear in what chemical form.

Water, Climate Evolution, and Habitability

Observational Clues

The amount of water present as gas and bound up with sulfuric acid and other compounds in the clouds is between 10 and 100,000 times less than exists in the oceans and atmosphere of the Earth. Thus, Venus is overall very dry compared to the Earth.

At the same time, ► [deuterium](#) (D) is about 100 times more abundant (relative to H) in the atmosphere of Venus than in that of the Earth. The discovery of this 150-fold enrichment in deuterium in the Venus atmosphere has traditionally been considered as evidence for the presence of significant amounts of water on early Venus, which would have been lost in the past (Donahue et al. 1982). Indeed, loss of water takes place by dissociation of the water in the

upper atmosphere by solar ultraviolet radiation and the subsequent escape of the ► [hydrogen](#). Both deuterium and normal hydrogen escape from the atmosphere, but the heavier isotope escapes less efficiently, leading to the observed isotopic fractionation.

Note, however, some authors have suggested that this enrichment could be explained by other mechanisms not requiring a planet very different than today (if one assumes that Venus started dry, the balance between cometary input and escape could create such an enrichment, Grinspoon 1987). New remote sensing measurements of the D/H ratio in the upper atmosphere above the clouds have revealed even higher D/H ratio (~ 240 times the terrestrial value). This may indicate shorter timescales for the loss of water from the top of the atmosphere than previously thought.

The Classical Scenario of Venus Evolution

Why is Venus so different from the Earth? Both planets formed at about the same time within the inner solar system, from similar chemical and isotopic reservoirs. Yet they have followed very different evolutionary paths. Unfortunately, as mentioned above, there are no direct geological records about Venus environment early in its history. The surface has been completely resurfaced a few hundreds of million years ago. Nevertheless, the presence of large amounts of water billions of years ago is expected by most planet formation models. Early conditions may have been more clement than today's extreme, in particular if the early Sun was as faint as expected by the standard Sun evolution models. Early Venus could have thus been covered by oceans of liquid water. As the Sun's luminosity slowly increased, these oceans warmed, more water evaporated to become part of the atmosphere, the greenhouse effect increased, enhancing water evaporation (positive feedback). Ultimately the entire oceans could have boiled. This process is termed the "runaway greenhouse effect." In reality, a full runaway greenhouse process may not have been possible because of moist convection and the high albedo produced by water cloud formation. However, it is likely that the ocean temperature was high enough to generate a relatively wet upper atmosphere ("moist greenhouse

effect”), so that water would have been rapidly lost by photodissociation followed by hydrogen escape (Kasting 1988). From then on, any carbon dioxide exhaled by volcanoes or delivered by impacts on Venus could no longer be removed from the atmosphere by chemical weathering (as on Earth) because of the lack of liquid water. As carbon dioxide accumulated in the atmosphere, the greenhouse effect grew ever more intense, leading to the planet that we know today. In particular, the lack of an ocean on Venus has at least three consequences for the atmosphere. First, most of the planet’s CO₂ remains in the atmosphere, in contrast to Earth, where most of the 50 bar of CO₂ are sequestered as carbonate rock in the sediments. Second, the atmosphere of Venus contains large quantities of SO₂. On Earth, most of the volatile sulfur resides in the ocean as sulfate ions. The presence of this large amount of SO₂ in the atmosphere is responsible for the production of a dense H₂SO₄ cloud on Venus. Third, the atmosphere of Venus contains large amounts of HCl. On Earth, the bulk of chlorine is in the form of salt (NaCl) in the oceans. The photochemistry of the atmosphere of Venus is driven by the catalytic chemistry of chlorine in the atmosphere.

Nowadays, Venus’ climate may also experience some variations, not because of changes in orbital parameters or obliquity (see ► [Mars](#)) but due to volcanic events that may have resulted in the release of atmospheric water and sulfur dioxide which was able to affect the atmospheric greenhouse effect and the cloud properties (Bullock and Grinspoon 2001).

Astrobiology of Venus

Present-day Venus’ surface is clearly hostile to carbon-water-based organisms. Nevertheless, it can be noted that the cloud layer between 50 and 60 km presents temperatures and pressures similar to Earth conditions (temperature ranging between –20 °C and +40 °C, pressure between 200 and 1000 mbar). Some have speculated that some microbial life could thrive in this aqueous, energy-rich environment with abundant nutrient and radiative energy. Some extremophile ► [archaea](#) observed on Earth could cope with the extreme acidity. However, a major issue lies in the

fact that the residence time of cloud droplets is limited. Because of that, for instance, there is no obvious bioactivity in terrestrial clouds (some bacterial growth has been reported, though). From that point of view, the residence time of Venus cloud particles is significantly longer than on Earth (months vs. days). Therefore, although the suggestion of life forms in Venus clouds remains a wild speculation which is not widely accepted, it remains difficult to prove it wrong at this time.

Venus’ interest for astrobiology goes beyond such speculations. For instance, the CO₂ dominated atmosphere of Venus may be an analog to the conditions of Earth’s earliest atmosphere, when the origin of life is believed to have taken place. It may also resemble the atmospheres of many extrasolar terrestrial planets. In the past, Venus may once have had warm, habitable oceans. The duration of this phase is poorly understood, but during this time, the terrestrial planets were not isolated. Rather, due to frequent impact transport, they represented a continuous environment for early microbial life. Venus may even have been a special place in the past, because the evaporation of these oceans, and subsequent escape of hydrogen, might have resulted, at least temporarily, in an oxygenated atmosphere.

More generally, Venus as we know it is the product of the evolution of an earthlike planet that formed at nearly the same distance from the Sun and is of similar age, size, and composition as the Earth. Therefore, the physics governing the state and recent evolution of its atmosphere are of high interest in understanding how the atmospheres of potentially habitable, earthlike planets evolve to different states. Venus presents us with a unique opportunity for putting the bulk properties, evolution, and ongoing geochemical processes of Earth into a wider context.

Venus Clouds

François Forget
Institut Pierre Simon Laplace, Laboratoire de
Météorologie Dynamique, Université Paris 6,
Paris, France

Definition

The clouds of ▶ **Venus** completely enshroud the planet in a complex-layered structure lying

between 45 and 75 km above the surface of the earth. The cloud droplets are formed of sulfuric acid (H_2SO_4) mixed with typically 25% water, with droplet diameters ranging from less than 1 to over 30 μm . Depending on the altitude, their temperature ranges between $-50\text{ }^\circ\text{C}$ and $+80\text{ }^\circ\text{C}$. In theory, they could provide a ► [habitat](#) to adapted life-forms, but this remains an unlikely speculation.

Venus Clouds, Potential for Life

Sabrina Guilbon
LATMOS, IPSL, Paris, France

Keywords

Clouds · Venus · Life · Extremophile · Exobiology

Definition

From hypotheses describing habitability of the primitive Venus to observed current conditions in the Venusian cloud layers, the question of the potential presence of life in these clouds can be studied. Indeed, some analogies may be drawn to Earth life forms that live in extreme conditions.

Overview

Venus is located outside the habitable zone defined by Hart in [1979](#) and in which water is present in liquid form. Barnes et al. ([2016](#))

proposes to define a transition region in which the possible habitability gradually decreases rather than defining a strict border separating two completely different areas.

Despite the extreme unfavorable current conditions for the life development, the primitive Venus seems to present better conditions for the emergence of life.

Primitive Venus or Paleo-Venus

During its formation, Venus received the same inventory of volatile species as Earth, including water. The Deuterium/Hydrogen ratio (or D/H) allows to assert that Venus has lost an important quantity of water in its history. However, it is still difficult to determine when and what part of this loss occurred (Donahue [1999](#)). Some scenarios advocate an escape of water from the Venus' atmosphere during its formation following an early greenhouse effect (Luger and Barnes [2015](#)), while others propose the formation of an ocean that has entirely evaporated (Way et al. [2016](#)).

A three-dimensional model taking into account the relief of the planet allows the study of an ancient Venus. This model reveals that a moderate temperature is possible on the surface if Venus has a slower rotation period than 16 Earth days despite a solar flux 46–70% higher than what receives modern Earth (Way et al. [2016](#)). Thus the ancient Venus could have remained habitable 700 million years ago if there was a primitive shallow ocean.

Donahue and Russell ([1997](#)) estimates that the liquid water uniformly distributed on the early planet would have reached a height from 4 to 525 m.

Then, Venus experienced in its history a runaway of the greenhouse effect causing the vaporization of its primitive oceans (Hashimoto et al. [2008](#)). Despite their total evaporation, the oceans may have persisted for several billion years (Grinspoon and Bullock [2003](#)), leaving the possibility of an environment that is sufficiently merciful long enough for the development of life.

Habitable Area in the Clouds

The atmospheric conditions have sterilized Venus' surface. Any biosphere that may have

developed in the early history of the planet has therefore been destroyed. However, the idea of migrating microorganisms to a more habitable area could be possible. Life on Venus may continue today in the upper atmosphere where the temperature and pH are tolerable for known terrestrial extremophilic organisms. It is therefore an aerial habitable zone. The high atmosphere combined with the high acidity allowed to define a cloud habitability zone located between an altitude of 51 km (65 °C) and 62 km (−20 °C) altitude. On the other hand, if this narrow field is sterilized, there is no life reservoir at the surface to recolonize this habitable aerial area.

Using samples taken at 3106 m of altitude, Sattler et al. (2001) show that bacteria on Earth grow, reproduce and produce proteins at high altitudes in the atmosphere. According to the authors, the only limiting factor of life in the terrestrial clouds is the residence time. Unlike terrestrial clouds, Venusian clouds are stable and represent a global and continuous environment where aerosols are in suspension for several months instead of a few days compared to Earth. This stability allows a residence time of microbes much longer than on our planet which is ideal for microorganisms (Schulze-Makuch et al. 2013). As Schulze-Makuch points out in his article of 2004, the conditions are therefore more favorable to life in the clouds of Venus than in terrestrial ones.

In addition, super-rotation of clouds improves the potential of photosynthetic reactions by reducing the time of darkness. Moreover, even if the habitable zone is in the clouds, the solar flux does not seem to constitute an obstacle to life.

Solar Flux and Cosmic Flux

Ultraviolet rays are harmful to biological macromolecules. The maximum absorption in clouds is at 285 nm (near UV) which damages microorganisms but does not constitute an insurmountable obstacle to life as shown in the work of Dartnell et al. (2015). Some microbes such as cyanobacteria and *Deinococcus radiodurans* use mechanisms to repair their DNA and UV-sensitive proteins (Ehling-Schulz and Scherer 1999). Another example of adaptation to large UV rays

known on Earth is the *Fusarium alkanophylum* fungus.

Schulze-Makuch's et al. (2004) hypothesis is that a layer of liquid sulfuric acid which engulfs a nucleus of S₈ absorbs a significant portion of UV radiation encountered by microorganisms thus allowing it to survive. The use of S₈ against UV radiation as a protective layer by microorganisms would explain why absorption by hydrocarbons is not observed (Plummer 1969).

The cosmic radiations create a field of ionic radiation which is harmful for organic molecules. At 62 km of altitude, Venus receives 0.200 kg/cm² which is far less than what the Earth receives on its surface (1.033 kg/cm²; Schulze-Makuch et al. 2004). However, the Venusian biosphere could be exposed to more ionized cosmic radiation because this planet has no magnetic field and its orbit is closer to the Sun. In addition, the consequences of ion flux in clouds are still under study (Dartnell et al. 2015).

Terrestrial Extremophiles

Clouds are a real niche for microorganisms and not a simple way of transport between surfaces (Womack et al. 2010). In the terrestrial stratosphere, samples taken by space balloons have shown the presence of bacteria at these altitudes (Wainwright et al. 2003). The discovery of this biosphere has been confirmed by high-altitude aircraft flights (Smith et al. 2010).

In order for microorganisms to live, it is necessary to have available energy sources. Dartnell et al. (2015) lists the following ones: photosynthesis, possible absorption in the UV using the oxidation of hydrogen sulfide or the chemotrophic reduction of sulfate. Indeed, Schulze-Makuch et al. (2013) define a Venusian ecosystem that conjugates sulfur-oxidizing photoautotrophic organisms and sulfur-reducing chemotrophs.

In general, terrestrial extremophilic microorganisms live between 120 °C and −20 °C (Cavicchioli 2002). Acidophilic hyperthermophilic organisms have been found in warm acidic waters, such as *Acidianus infernus* (Segerer et al. 1986). These microorganisms have an optimal growth temperature of 88 °C and can live in an environment where pH is close to 0.5.

Although terrestrial analog sites do not offer a temperature and acidity comparable to that of Venus, there are terrestrial thermoacidophilic extremophiles known to tolerate both high temperatures and low pH named *archaea*. In this family of microorganisms, the most extreme organisms known to date are *Picrophilus* genus. These archaea grow at pH null or below zero for temperatures not exceeding 65 °C (Thürmer et al. 2011).

Despite all these terrestrial analogies, there is still no evidence to this day of extremophile terrestrial life for a pH~2 around 45 °C.

Earth-Like Life or New Life Forms Specific to Venus?

Based on the current understanding of Earth life and Venus environmental conditions, a life cycle of the Venusian aerial biosphere inside cloud droplets is proposed by Seager et al. (2020).

The acidity of the Venusian atmosphere increased during the first 600 million years after the formation of Venus (Kumar et al. 1983). Life forms may very well have evolved differently to gradually adapt to the acidic conditions of this planet.

To clarify the potential life existence in a rocky planet's atmosphere, the detection of phosphine (PH₃) was defined as a biosignature in exoplanet atmospheres (Sousa-Silva et al. 2020) as it can be produced on Earth by anthropogenic activity or microbial presence. The presence of this gas on Venus was reported by Greaves et al. (2021) and then some inconsistencies were raised by the study of Lincowski et al. (2021) that conclude that SO₂ is a more plausible explanation of the detected gas.

The unambiguous proof of the existence of life on Venus can only be established by a mission with return of samples taken from the cloud layer of Venus (Schulze-Makuch and Irwin 2002).

Definition

Venus Express was the first ESA mission to Venus, operational from 2005 to 2014. It performed a global investigation of the atmosphere and the plasma environment of the planet, and addressed several important aspects of geology and surface physics.

History

The first phase of Venus spacecraft exploration (1962–1985) by the Soviet Venera and Venera-Halley (VeGa) and American Pioneer Venus missions established a basic description of the physical and chemical conditions prevailing in the atmosphere and at the surface of the planet. At the same time, they raised many questions on the physical processes sustaining these conditions. Extensive radar mapping by the Pioneer Venus Venera-15, -16 and Magellan orbiters, combined with earlier glimpses from landers, have expanded considerably our knowledge of Venus' geology and geophysics. By the end of 1990s a similar systematic survey of the atmosphere with particular emphasis on its lower part below the clouds was due. In March 2001 ESA issued a *Call for ideas* from the scientific community on a reuse of the spacecraft platform developed for the Mars Express mission, equipped by “off-the-shelf” instruments. In 2002 Venus Express was selected as the winning proposal. The MEX spacecraft design was adapted to the Venus environment and then built by the industrial team led by EADS Astrium, now Airbus Defence and Space. The science payload was mainly inherited from Mars Express and Rosetta missions complemented by instruments specifically designed and built for Venus Express. Due to reuse of the platform elements and payload the

Venus Express,

Fig. 1 Preparation of the Venus Express spacecraft for vibration tests in summer 2005 at Intespace facilities in Toulouse, France. (Credit: EADS Astrium)

spacecraft was built in only 33 months – a remarkably short period of time for such a complex mission (Fig. 1).

Basic Methodology

Science objectives. The mission overarching theme was to perform a global investigation of the atmosphere and plasma environment of the planet and to address several important aspects of the geology and surface physics. It was broken down into several top-level science objectives: (1) vertical structure of the mesosphere and upper troposphere; (2) general circulation and dynamics; (3) morphology and structure of the clouds and hazes; (4) composition and chemistry of the mesosphere and upper troposphere; (5) radiative energy balance; (6) aeronomy, plasma

environment, and escape processes; and (7) limited studies of geology and surface properties.

Orbit and scenario. Venus Express was launched on 9 November 2005 by a Russian Soyuz-Fregat launcher from the Baikonur cosmodrome in Kazakhstan. After the orbit insertion on 11 April 2006 the spacecraft successfully operated until 17 December 2014 making it the longest duration mission at Venus so far. The highly elliptical ($250 \times 66,000$ km) near-polar 24-h orbit was specifically chosen to combine global monitoring with close-up views of the planet. The orbit enabled the instruments to observe almost the entire planet over a full Venusian day (243 Earth days). Venus Express became the first ESA spacecraft to perform aerobraking reducing the orbital period from 24 h to just under 22 h 30 m. Venus Express performed innovative investigation of atmospheric densities in the polar

Venus Express,

Fig. 2 Sketch of the Venus Express orbit. Figures along the orbit show the time since pericenter passage (orbital time). (From Titov et al. 2008)

regions by measuring accelerations and torques exerted on the spacecraft at altitudes from 130 to 200 km during pericenter passes. This resulted in a large dataset over an extended period and has enabled sounding of the atmospheric structure in an altitude range not probed by conventional remote sensing (Fig. 2).

Spacecraft. The Venus Express spacecraft design was based on the successful Mars Express bus – a 600 kg three-axis stabilized platform $1.7 \times 1.7 \times 1.5$ m in size with two body-fixed telecommunication antennas. The spacecraft carried about 600 kg of fuel used for maneuvers, orbit insertion, and keeping. The spacecraft subsystems and payloads were mounted on its walls and on the panels inside the bus. The apertures of the optical instruments were located on +Z face pointing to the planet during observations (Fig. 3).

Payload. The scientific payload of Venus Express, summarized in the table below (Table 1), comprised seven instruments. Four of

these were reused “as is” or slightly modified versions from Mars Express, and three of them were adapted from ESA’s Rosetta mission. The PFS instrument was not operational due to a failure of the pointing mechanism.

Key Research Findings

Venus Express provided observations of the atmosphere and plasma environment from 2006 to 2014 making breakthroughs in many science topics.

Atmospheric vertical structure. The vertical structure of the lower thermosphere through the upper troposphere (160–40 km) was studied by a combination of radio and solar occultation, thermal emission spectroscopy, and drag experiment (Limaye et al. 2018a). The mesospheric thermal field is characterized by a general temperature decrease with altitude and presence of a “cold

collar” – an annulus of cold air surrounding the planet at 50–75° latitude and about 65 km altitude in both hemispheres previously discovered by Pioneer Venus and Venera-15, -16 (Fig. 4). This region is characterized by strong temperature inversions at the cloud top. The temperature field showed significant local time variability.

Venus Express performed unique measurements of atmospheric density and temperature in the lower thermosphere (160–100 km) discovering a very cold layer at ~125 km and a strong variability at these altitudes. More than 800 radio occultations revealed fine details of the atmospheric structure at 40–90 km at few 100 m

Venus Express,

Fig. 4 Average temperature latitude–altitude cross-section of the Venus mesosphere derived from VIRTIS-M dataset. (From Limaye et al. 2018a)

vertical resolution indicating, in particular, that the region below the cloud base is convectively unstable in polar regions (Ando et al. 2020).

Morphology and structure of the clouds and hazes. Venus Express made significant progress in our understanding of the clouds and hazes by exploiting imaging instruments covering a spectral range from UV through thermal IR, spectroscopy in solar and stellar occultation geometry enhanced by the long duration of the mission and its highly elliptical polar orbit (Titov et al. 2018). The upper haze extending from the cloud top (70 km) to ~90 km is rather uniform over the planet and has scale height $H_a = 2.8 \pm 1.2$ km at $20\text{--}80^\circ\text{N}$ with a trend to increase to 4.4 ± 1.0 km at the pole. The aerosol population consists of sulfuric acid particles of up to $1\text{ }\mu\text{m}$ in radius. Below 75 km the scale height increases to 4–5 km at low and middle latitudes, while in polar regions the cloud top is very sharp ($H_a < 1$ km). Spectroscopic observations by VIRTIS and SPICAV found the cloud top at ~72 km in low-to-middle latitudes descending to ~64 km at the poles (Fig. 5).

Venus Express was the first orbiter exploiting near-infrared spectral transparency “windows” on the nightside that provided indirect constraints on the properties of the deep cloud. The cloud base in high latitudes was found to extend down to ~45 km (Oschlisniok et al. 2021), much lower than in the low and middle latitudes, with much greater total opacity at high latitudes.

Morphology of the upper clouds is the most prominent at UV wavelengths (Fig. 6). The observed contrasts reach ~30% due to nonuniform distribution of an unknown absorber in the upper cloud. The low latitudes are on average much darker than polar regions. Total opacity variations mainly formed in the deep cloud (~50 km) produce the features seen in the near-IR images on the nightside. Global cloud pattern at all altitudes indicates vortex-type circulation with air masses spiralling from equator to poles.

Figure 7 shows the structure and main properties of the Venus cloud and haze system.

Atmospheric circulation and dynamics. Several cameras on board Venus Express continuously imaged the planet in different spectral ranges on both day and nightside that allowed monitoring of the cloud motions at different altitudes thus providing “tomography” of the atmospheric circulation (Sánchez-Lavega et al. 2017).

The mesosphere and troposphere (0–100 km) are dominated by fast zonal retrograde (westward) motions called super-rotation (Fig. 8). In the low-to-middle latitudes ($0^\circ\text{--}55^\circ$) the zonal winds are weakly dependent on latitude but significantly change with altitude indicating a vertical wind shear of 2–3 m/s/km. Poleward of $\sim 60^\circ$ the zonal wind subsides. The apparent convergence of the wind profiles in Fig. 8 (upper panel) suggests either absence of a vertical wind shear or, more likely, a much denser aerosol media (Titov et al. 2018) that results in sounding of almost the same

Venus Express,

Fig. 5 Mean cloud top altitude in the Southern Hemisphere. (From Titov et al. 2018)

Venus Express, Fig. 6 Venus false color view consisting of VMC UV (365 nm) (grey) and VIRTIS near-IR (1.7 μ m) (red-black) images simultaneously taken on the day and nightsides. (From Titov et al. 2018)

altitude levels at all wavelength from UV through near-IR. The meridional winds (Fig. 8, lower panel) show a poleward velocity of 5–10 m/s at the cloud tops and a return flow in the deep cloud, thus indicating a Hadley cell encompassing the cloud layer at least in the low-to-middle latitudes.

Venus Express elliptical polar orbit with its apocentre above the Southern pole (Fig. 2) was very well suited for characterization of the polar dynamics that was not explored by the previous missions. The latitudes above 60° feature a polar vortex – a highly dynamic whirl-pool-like structure centered within few degrees from the pole and rotating with the period of 2–2.5 days shorter than the super-rotation of the atmosphere at low-to-middle latitudes. The vortex region is characterized by a very low cloud top (~62 km) and relatively high temperatures (Fig. 9).

Long-term monitoring of the atmospheric motions by Venus Express revealed variabilities in the circulation pattern at different temporal and spatial scales. They include thermally driven acceleration of the zonal winds by 5–15 m/s at the cloud top at low latitudes in the afternoon, signs of a planetary 4-day Kelvin and 5-day Rossby waves, and annual acceleration of the zonal circulation likely related to large-scale surface topography.

Venus provides a unique example of a slowly rotating planet that makes Coriolis force and its impact on atmospheric dynamics negligibly

Venus Express, Fig. 7 Sketch of the Venus clouds latitude-altitude structure: upper haze (light blue), upper cloud (yellow “droplets”), middle and lower clouds (blue “droplets”), and lower haze (red “droplets”). Black contours show isolines of the Venera-15 temperature field.

Blue, green, and red solid lines mark the cloud top ($\tau = 1$ level), the tropopause, and the cloud base, respectively. Composition and mean microphysical parameters of the cloud layers are shown in semitransparent inserts. (From Titov et al. 2018)

small. The general circulation of the Venus atmosphere, and in particular zonal super-rotation, is controlled by so-called cyclostrophic balance – approximate equality between centrifugal and pressure gradient forces. Thus, the zonal wind field is strongly correlated with pressure and temperature.

Composition and chemistry. Venus Express delivered pioneering results on the composition of the mesosphere and troposphere due to extensive exploitation of high-resolution spectroscopy in solar occultations and use of the novel technique of sounding the atmosphere below the clouds in spectral transparency “windows” on the nightside (Marcq et al. 2018; Chamberlain et al. 2020).

Figure 10 shows the summary of the Venus Express composition measurements. They revealed strong decrease by one to two orders of magnitude of the sulfur dioxide (SO_2) and water vapor (H_2O) abundance through the clouds resulting from the photochemical formation of sulfuric acid at the cloud tops. Furthermore, the abundance of SO_2 above the clouds was found to vary over two to three orders of magnitude. The mean abundance exhibited a fourfold rise during

the first year of Venus Express observations, and a tenfold decrease during subsequent years, a pattern which could be due to active volcanism or to intrinsic dynamics. Carbon monoxide (CO) shows the opposite trend of increasing mixing ratio with altitude due to photochemical production of this molecule above the clouds. Gaseous sulfuric acid (H_2SO_4) was sounded in the radio-occultation experiment at the cloud bottom where cloud droplets evaporate. Venus Express provided measurements of halides (HCl and HF) in the mesosphere that play an important role in chemical processes. Simultaneous measurements of H_2O and its heavy isotope HDO showed an even larger D/H ratio in the mesosphere than that measured before in the lower atmosphere: 240 ± 25 relative to the ratio on Earth. Strong enhancement of the Venus atmosphere with heavy isotope suggests presence of much larger amount of water on the planet in the past. The composition measurements indicated strong spatial and temporal variations of minor species pointing to various chemical and dynamical processes that will be understood in extensive simulations of the Venus atmospheric chemistry.

Venus Express,

Fig. 8 Global mean zonal (upper panel) and meridional (lower panel) winds measured in UV (blue), visible (green), and 1.74 μm (red) that correspond approximately to 70, 62, and 55 km at least in the low-to-middle latitudes. (From Sánchez-Lavega et al. 2017). The negative (positive) meridional winds correspond to poleward (equatorward) motions. The shaded areas show variability of the wind profiles. (Credit: R. Hueso, private communication)

variabilities. Solid bars show nadir soundings. Dotted lines are linear extrapolations between different types of measurements

Aeronomy and ionosphere. Venus Express collected a wealth of data about the thermosphere and ionosphere of the planet. The mission mapped the nonthermal emissions (airglow, nightglow, and fluorescence) from the upper atmosphere with high spectral resolution from UV through middle-IR range that allowed characterization of the atmospheric structure and dynamics at 150–90 km, the altitude range poorly sampled before. Mapping of the O_2 nightglow at $1.27\ \mu\text{m}$ revealed its vertical structure peaking at ~ 100 km and spatial distribution (Fig. 11). The latter implies that the at this altitude the thermospheric circulation that supplies oxygen ions from the day side is almost entirely subsolar-antisolar. However, similar observations of NO emission that peaks at ~ 115 km show the shift of the emission peak by several hours local time likely suggesting significant super-rotation component of the circulation. Venus Express observations in Lyman- α confirmed that the planet's hydrogen corona is dominated by the nonthermal population at high altitudes.

More than 800 radio-occultations by Venus Express allowed detailed characterization of the ionosphere and its variability with solar activity, local solar time, and latitude.

Plasma environment and escape. Venus Express was equipped with an ion and neutral particle spectrometer ASPERA-4 to characterize the plasma population in situ and a magnetometer MAG to measure the magnetic field (Futaana et al. 2017). The mission carried out unique investigations of plasma environment in the polar and terminator regions down to altitudes of ~ 250 km through a long and deep solar minimum, and probed the magnetic field to ~ 130 km as it made its final entry. For the first time it probed the plasma tail, the region hosting dynamic processes that lead to plasma energization and escape of ions to space. Venus Express studied topology of the plasma boundaries and response of the magnetospheric system to the solar wind conditions on different time scales. The first-ever energetic neutral atom measurements revealed the neutral exosphere and solar wind plasma interaction near Venus. A plethora of waves was identified by the magnetometer: proton cyclotron waves upstream of the bow shock, mirror mode waves in magnetosheath, and whistler mode waves, possibly generated by lightning discharges.

Venus Express found that planetary ion escape with energy of ~ 10 eV to ~ 10 s of keV occurs in

Venus Express,

Fig. 11 Map of the O₂ nightglow intensity. Antisolar point (midnight at equator) is in the middle of the planet disc. (From Gérard et al. 2017)

Venus Express, Fig. 12 Spatial distribution of the heavy ion flux. (From Futaana et al. 2017)

the solar wind wake and adjacent magnetosheath (Fig. 12). Ion mass separation capability allowed the ASPERA-4 particle instrument to determine that H⁺ and O⁺ ions escape in stoichiometric ratio of the water molecule, implying that water is still lost by the Venus atmosphere at a rate of (3–6) 10²⁴ molecules/s in the solar minimum epoch. The flux is almost doubled during high solar activity events (e.g., coronal mass ejection). It is notable that the escape flux at Venus appears to be smaller than that from Earth, despite Venus' proximity to the Sun and its lack of a magnetic field; this finding challenges the common assumption that planetary magnetic fields provide a shielding effect reducing atmospheric loss. These results are of great importance for comparative planetology since Venus is a nonmagnetic Earth-size planet.

Surface and activity. Although Venus Express was not specifically designed for surface

investigations, some observations provided important evidences of surface mineralogy and recent geological activity (Gilmore et al. 2017). VIRTIS and VMC cameras were capable of mapping weak nightside emissions around 1 μm leaking from the hot surface though the thick atmosphere. Low surface emissivity on tesserae, different from that observed on basaltic plains, was found consistent with felsic rocks, showing similarities to Earth's continental crust. VIRTIS also discovered regions with relatively high surface emissivity spatially associated with coronae, volcanoes, and lava flows indicating low weathering and thus geologically young (0.25–2.5 MYears) units. Transient high thermal emission events were detected by the VMC camera in the Ganiki Chasma rift zone indicating surface-elevated temperatures consistent with fresh lava flows (Shalygin et al. 2015). These observations indicating geologically recent and

even ongoing geological activity paved a way for future investigations by ESA's EnVision and NASA's VERITAS and DAVINCI+ missions to Venus.

Habitability. The proximity and similarity of Venus to Earth make the planet a very attractive target in terms of astrobiological exploration. Limaye et al. (2021) has recently presented a case for the exploration of Venus as an astrobiology target using four lines of argumentation: (1) likelihood that liquid water existed on the surface in the past; (2) existence of the habitable zones within Venus' present-day clouds; (3) theoretical investigations into how active aerobiology may impact the radiative energy balance of Venus' clouds and Venus-like atmospheres; and (4) application of these investigative approaches toward better understanding the atmospheric dynamics and habitability of exoplanets.

Several results of Venus Express addressed the history of water on Venus. The SPICAV experiment found the D/H ratio above the clouds to be 240 ± 25 times higher than Earth's (Marcq et al. 2017) implying a significant loss of water to space over time. The discovery of low $1 \mu\text{m}$ emissivity in highland regions, as described above, indicates an iron-rich (felsic) composition of the highlands, interpreted as being potentially consistent with a water-rich past environment (Gilmore et al. 2019). Persson et al. (2020) used in situ ion measurements by ASPERA-4 to quantify the escape rates of oxygen ions at different conditions. Extrapolation of the current escape rates back in time led to the conclusion that the total amount of water loss was only 0.02–0.6 m of a global equivalent layer, suggesting that present-day ion escape alone cannot account for the loss of an historical Earth-like ocean.

As to present habitability, Venus Express significantly contributed to our understanding of the Venus clouds, where relatively benign environmental conditions are found. In the upper clouds, one of the long-standing mysteries is the identity of the UV absorber which is responsible for absorption of a large fraction of the solar energy absorbed by the planet (Titov et al. 2018; Limaye et al. 2018a). Limaye et al. (2018b) presented an interesting hypothesis suggesting that cloud-

based microbial life could be contributors to the spectral signatures of Venus' clouds, building upon previous suggestions of the possibility of life in the clouds of Venus relying on the origin of life on Venus occurring when it presumably had liquid water oceans (Schulze-Makuch and Irwin 2002). Venus Express conducted detailed mapping of the spatial distribution of the UV absorption, and measured variations in the refractive index of the cloud top, by measuring the phase function which describes how it reflects light. This showed greater variability than could be explained by sulfuric acid clouds alone, leading investigators to suggest minority cloud constituents including FeCl_3 and elemental sulfur (Titov et al. 2018). However, a detailed measurement of cloud composition is not possible from orbit and will require future measurement in situ.

Applications

In several respects Venus Express was a pioneering mission that for the first time applied novel observation techniques. The mission provided global monitoring of the composition of the lower atmosphere from orbit using spectroscopy of weak emissions leaking from the lower atmosphere on the nightside. It also exploited very-high-resolution spectroscopy in solar occultation geometry to scrutinize composition of the mesosphere above the clouds. Imaging in a broad spectral range as well as extensive use of the radio-occultation sounding significantly advanced our understanding of the atmospheric dynamics and cloud morphology. Surface mapping at thermal wavelengths led to the discovery of surface emissivity anomalies suggesting geologically young features and even evidence for active volcanism today. The 3D ion mass analyzer, high-energy resolution electron spectrometer, and energetic neutral atom imager supported by a magnetometer allowed for the first time to study plasma environment and escape at Venus. And finally, Venus Express was the first ESA spacecraft to perform aerobraking at Venus, thus paving a way to future missions (e.g., EnVision). Future missions to Venus will strongly benefit

from the novel observation and mission-enabling techniques validated and extensively used by Venus Express.

Future Directions

Despite many successful spacecraft missions to Venus many fundamental questions remain unanswered. We still do not understand Venus tectonics, mechanisms of heat release from the interiors, surface composition, formation of geological features, and whether the planet is still volcanically active. The mechanisms driving atmospheric super-rotation, composition, and chemical cycles that form the clouds and its interaction with the surface are still poorly understood. Important details of the processes in the upper atmosphere and especially those responsible for atmospheric escape are still missing. However, many of the investigations and results from Venus Express have informed and inspired plans for follow-up investigations. Many of the findings from Venus Express are now being investigated in more detail by JAXA's Akatsuki orbiter, in particular in the fields of atmospheric dynamics and cloud morphology (Nakamura et al. 2018). Venus Express surface and atmosphere observations will be further developed by missions recently selected for implementation in the next decade: ESA's EnVision and NASA's VERITAS orbiters, NASA's DAVINCI+ entry probe, and possible future landers and cloud-level balloons.

Venus Missions (History of)

Michel Viso
Innovaxiom, Paris, CX, France

History

To date, 46 missions or spacecraft have been launched toward Venus, 40 of them aim to fly by, orbit, impact, or land on Venus. Out of 29 missions launched by the Soviet Union between 1961 and 1989, 14 have been successful or almost successful. The second mission Venera1, launched on February 12, 1961, was the first spacecraft to fly by another planet. Seven missions have been launched by the United States: One failed, and the others have been successful. The operational success does not mean that each time the science reward was at the level of the expectancy. One of the 3 Japanese missions,

Akatsuki, failed its insertion in Venus orbit on December 6, 2010. The JAXA developed a recovery plan, and the probe was inserted in the orbit on December 7, 2015, and is still operational in 2022. Venus Express is the sole mission to Venus launched by ESA (November 9, 2005) and was operational during almost 9 years. In 1984, Vega 1 and Vega 2 have been launched 1 week apart in December 1984 to deliver landers while the spacecrafts continue to achieve flybys of the comet 1PHalley in 1986.

Six missions have been launched toward Venus to benefit of a gravity assist to accelerate toward the gaseous giant planets (Galileo to Jupiter and Cassini to Saturn), to be directed toward Mercury (Messenger and BepiColombo), or to change the inclination of the probe orbit around the sun (Parker Solar Probe and Solar Orbiter).

Six missions are under development in United states (3), India (1), Europe (1), and Russia (1) slated to be launched between 2023 and 2029.

Several scientists' plea to explore Venus as a target of interest for astrobiology (Limaye et al. 2021) considering that the planet could have had liquid water on the surface in its early history, allowing the possible development of a form of life. Some clouds of the planetary atmosphere could be considered, presently, as potentially habitable. Finally the investigations about the energy balance and the dynamic evolution of the planet atmosphere are of interest to prepare the study of potential Venus-like and telluric exoplanets.

Vernadsky

Stéphane Tirard

Faculté des Sciences et des Techniques de Nantes,
Centre François Viète d'Histoire des Sciences et
des Techniques EA 1161, Nantes, France

History

Vladimir Ivanovitch Vernadsky (1863–1945) was a Russian geochemist scientist born in Saint Petersburg, who introduces the new concept of biosphere. In 1926, he wrote an important book, entitled precisely *The Biosphere*, formulating new ideas related to Earth as a global dynamic system. The concept of biosphere describes the relationships between living beings and the physical chemical and energetic aspects of the environment.

Vernadsky's contributions were broadly transdisciplinary with geology, chemistry, biology, and physics (notably with thermodynamics). His work constituted an important step to the ecology history.

Vernal Point

Daniel Rouan

LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The vernal point is one of the two equinoctial points on the celestial sphere. The ► [celestial equator](#) and the ► [ecliptic](#) plane intersect at those two points which are crossed by the Sun at each ► [equinox](#). The vernal point is the one

corresponding to the spring equinox. The vernal point is the origin of the ► [right ascension](#) coordinate in the equatorial system of coordinates used by astronomers.

of Technology, Atlanta, GA, USA

Definition

A vesicle in biology is a small organelle within a cell consisting of fluid enclosed by a membrane that can store or transport substances. When prepared artificially they are generally called liposomes. They can be formed from a wide variety of surfactants including simple fatty acids and

mixtures of fatty acids and fatty alcohols. In living organisms, most vesicles have specialized functions depending on what materials they contain. Vesicles are used in the cell to store, transport, or break down cellular products and waste. The membrane enclosing the vesicle is similar to that of the ► [cell membrane](#), and vesicles can fuse with the plasma membrane to release their contents outside of the cell, in a process known as exocytosis. Vesicles can also fuse with other organelles within the cell.

German Aerospace Center (DLR), Institute of
Planetary Research, Berlin, Germany

Keywords

Asteroids

Definition

► [Asteroid](#) (4) Vesta is the second most massive and third largest object in the ► [main asteroid belt](#). It has an orbit with moderate ► [eccentricity](#) (0.09°) and ► [inclination](#) (7°). The length of its semimajor axis is 2.36 AU and the orbital period is 3.62 years. It is one of the very few asteroids occasionally visible to the naked eye. The International Astronomical Union (IAU) is presently considering whether to include Vesta in the newly defined class of ► [dwarf planets](#). Dawn, the NASA Discovery mission, has been orbiting Vesta from July 2011 to September 2012, mapping its surface and gravitational field.

History

Vesta was discovered on March 29, 1807, by Heinrich Wilhelm Olbers from the German city of Bremen and named after the Roman goddess of the hearth. It was the fourth object discovered in the main belt – after (1) ► [Ceres](#), (2) Pallas, and (3) Juno – and is the brightest one. Therefore, Vesta was also long thought to be the largest asteroid, until in 1900 E.E. Barnard showed by directly measuring the size of the disk of the first four asteroids that the higher brightness of Vesta was due to its high ► [albedo](#).

Overview

The shape of Vesta is approximately that of an oblate spheroid with semiaxes of 285 and 229 km, respectively. It shows a complex and substantial topography, with a relief-to-size ratio of about 15%. Vesta's shape is dominated by a giant impact basin located at the south polar region, named Rheasilvia, with a central mound. The Rheasilvia event obliterated preexisting craters in the southern region, thereby producing a North-South dichotomy, with the two hemispheres showing differences in terms of crater density, colors, and albedo. A system of concentric equatorial troughs that encircle the entire body is also thought to be associated with the Rheasilvia and a similarly large preexisting basin – Veneneia. Already Earth-based spectral observations (McCord et al. 1970) had shown that Vesta has a basaltic surface, which implies that the body experienced igneous ► [differentiation](#). This is thought to imply the formation of a basaltic ► [crust](#), an olivine-rich ► [mantle](#), and a metallic core. This finding has been confirmed by the Dawn measurement of the J_2 gravitational moment, which is compatible with the presence of a metallic core of about 110 km in radius.

The surface of Vesta is highly variegated, with a broad range in albedo. Dark regions are generally, but not always, associated with impact craters and can have albedos as low as 10%. It has been suggested that these dark spots are of exogenic origin and represent the remnants of carbon-rich impactors. The brightest regions can have an

albedo as high as 67%, are in general associated with crater walls, and probably represent underlying brighter material exposed as a result of surface processes.

It is believed that a class of meteorites found on ► [Earth](#), the Howardite, Eucrite, and Diogenite, or HED ► [meteorites](#), originated from Vesta, possibly from the Rheasilvia region. With the discovery of a class of asteroid (Vestoids) sharing the same surface spectral properties as Vesta, and spanning the gap between Vesta's ► [orbit](#) and the 3:1 mean motion resonance with ► [Jupiter](#) that provides a viable route to Earth, this hypothesis has been widely accepted by scientists.

Vesta was among the first bodies that formed in the ► [Solar System](#). Radioisotope chronology from the HED meteorites suggests it accreted in only 5–15 million years. Vesta is therefore one of the few original objects in the main asteroid belt that has escaped collisional destruction.

Viking

François Forget
Institut Pierre Simon Laplace, Laboratoire de
Météorologie Dynamique, Université Paris 6,
Paris, France

Keywords

Mars · NASA

Definition

Viking is the name of two missions launched by ► [NASA](#) in 1975 to explore ► [Mars](#). Each mission consisted of an orbiter and a landing probe. The two missions were successfully inserted in orbit around Mars and the surface probes landed successfully.

History

Emboldened by the success of Mariner 9 in 1971, NASA set itself the goal of placing a module on

the surface of Mars. Engineers at the Jet Propulsion Laboratory (► [JPL](#)) were conscious that, although the Soviets had been successful with their missions to Venus, an apparently far more inhospitable planet, their Mars effort had seen far fewer rewards.

Overview

With this in mind, NASA's preparations for their Viking missions were exhaustive: two identical spacecraft, weighing 3527 kg each, were launched on August 20 and September 9, 1975. They consisted of a Mariner-type orbiter, coupled with a lander weighing more than 1 t. This would be one of the most complex and costly explorations ever undertaken by NASA. The precautions were worthwhile: the ten-month journey to Mars went without a hitch. Viking 1 entered Mars orbit on June 19, 1976. Its instruments (cameras, infrared radiometer, and water vapor detector) were deployed, searching for an ideal landing site: "not too high, not too windy, not too sloping, not too rocky, not too dusty, not too near the pole." It was almost impossible to find such a site from orbit, and NASA had to delay the landing (originally planned to coincide with the American Bicentennial on July 4; national pride was

eventually satisfied, however, in 1997, when Mars Pathfinder landed on that date). Viking 1 finally touched down in triumph on July 20 (the eve of Belgium's National Day!), on Chryse Planitia, at latitude 22 °N. It just missed, by a few meters, a large boulder that could have ended the mission there and then. Images of Mars as seen from its surface became front-page news, but the primary objective of the mission was the search for life. As the days went by, the scientists overseeing the Viking experiments pieced together their conclusions: officially, "no life," but unanimity was lacking. Like its sister ship, Viking 2 landed unhindered, this time on the other side of the planet on the plain of Utopia, at latitude 48°N. The results of its experiments were the same. Nevertheless, the Viking mission was counted a success: The expected working lifetime of the modules was 90 days, but they continued to render loyal service for more than 6 years. The last contact, with Viking 1, took place on November 13, 1982 (Figs. 1 and 2).

Basic Methodology

The Viking Landers

Before landing, the Viking landers passed through the Martian atmosphere at more than 4 km/s,

Viking, Fig. 1 Viking lander in its bio-shield ready to be heated up to 111.7 °C for 30 h

Viking, Fig. 2 Viking 2 lander color image looking south of spacecraft and Utopia Planitia

protected and decelerated by its heat shields. At 6000 m, a giant 18-m-wide parachute, suitable for Mars' thin atmosphere, was deployed. As happened earlier with the lunar modules, retro-thrusters slowed the lander during the last few hundred meters of its descent, autopiloted by the onboard radar. Before leaving Earth, the two probes had been carefully sterilized, so that Mars should not be contaminated, in accordance with the outer space treaty (OST). On the surface, a plutonium-based radioactive source provided energy for the module. A parabolic antenna was used for communications with Earth, either direct or relayed via the orbiters. As well as cameras and the necessary equipment for biological experiments, the Viking landers also had meteorological instruments, a mass spectrometer, and an X-ray fluorescence spectrometer for chemical analysis and a seismometer.

The Viking Orbiters

The orbiters monitored the surface and the atmosphere of ► [Mars](#) until July 25, 1978 (orbiter 2), and August 7, 1980 (orbiter 1). They were using color cameras (the highest resolution obtained was 7.5 m), the Mars Atmospheric Water Detectors (MAWD), and the Infrared Thermal Mappers (IRTM) which mapped the surface and the atmospheric temperature as well as the surface ► [Albedo](#) and thermal inertia.

Key Research Findings

The Viking Landers' Search for Life. The detection of life on the Martian surface was one of the main objectives of the Viking probes. An articulated arm, capable of digging into the surface, gathered samples of Martian soil. The samples were subjected to three investigations: the pyrolytic release, gas exchange, and labeled release experiments:

- The *pyrolytic release* experiment was designed to check if possible Martian organisms would assimilate carbon dioxide, as certain terrestrial organisms do (photosynthesis). No such activity was detected.
- The *gas exchange* experiment was designed to detect gas produced by microorganisms having digested organic matter. Quite a lot of oxygen was detected, but as it was still being produced after sterilization by heating the sample to 145 °C, it was concluded that the oxygen came from the chemical oxidization of the material. Rather than detecting life, the experiment showed that the surface of Mars is an oxidizing and sterilizing milieu, rather like some medical disinfectant.
- The *labeled release* experiment was designed to detect, by radioactive marking, the transformation of organic matter into carbon dioxide.

The result proved positive: There was indeed a transformation, which ceased as soon as the sample was heated – exactly what one might expect if bacteria were present.

- In case of the *GCMS*, however, the verdict was finally negative, because another instrument, *a gas chromatograph coupled with a mass spectrometer*, capable of detecting organic molecules at a concentration below one part per billion, found nothing, to the surprise of all concerned.

In the light of the other experiments, most of the experts, though not all, concluded that the labeled release experiment was evidence of the chemistry of inorganic processes in an oxidizing environment. The surface of Mars seems to have been completely purged of all natural organic matter by ultraviolet radiation and oxidization.

More recently, the Viking GCMS measurements have been re-analyzed in light of the Phoenix lander and Curiosity rover observations. Evidence for chlorobenzene have been found (Navarro-González et al. 2010; Guzman et al. 2018) like with Curiosity, and it has been suggested that the oxidation by Martian perchlorates during pyrolysis could explain why Viking did not detect more organic molecules.

Vinyl Cyanide (CH₂CHCN)

William M. Irvine

Department of Astronomy, University of Massachusetts, Amherst, MA, USA

Synonyms

[2-propenenitrile \(IUPAC name\)](#); [Acrylonitrile](#); [CH₂CHCN](#); [Cyanoethane](#)

Definition

Under standard conditions in the laboratory, vinyl cyanide is a colorless liquid that is highly flammable and toxic. It is commonly observed by radio astronomers in the “hot cores” of interstellar clouds, which are the sites of the formation of massive stars, and it has also been detected at lower abundance in cold interstellar clouds and in the envelopes of evolved, carbon-rich stars. Observations at millimeter wavelengths detect the pure rotational transitions in the ground vibrational state and in low-lying vibrational states; 13-carbon isotopic species have also been detected in molecular clouds (Müller et al. 2008).

History

Interstellar vinyl cyanide was first detected in the interstellar medium by Gardner and Winnewisser (1975). It has also been observed in the atmosphere of Saturn’s satellite Titan (Cordiner et al. 2018).

the modified host cell membrane. In most animal and plant virus families, non-enveloped or “naked” virions show either icosahedral or helical symmetry. In turn, enveloped virions as well as those that infect bacteria and archaea usually show complex shapes. Virions typically range in size from about 20 to 300 nm, although certain viral families that infect amoebas produce larger virions.

Small RNAs

Definition

Viroids are independently replicating circular RNAs of small size (246–401 nucleotides), with compact secondary structure, without protein-coding capacity, and capable of infecting and causing disease in plants. Viroids bear some resemblance with other two replicons: (1) viroid-like satellite RNAs, often called virusoids, which are structurally similar to viroids but dependent on coinfecting helper viruses for replication and transmission, and (2) human hepatitis delta virusRNA, which is also circular and highly structured, but with a size fourfold larger than that of

the largest viroid, coding for a protein in the antigenomic polarity and depending on hepatitis B virus for assembly and transmission.

Overview

Viroids are the minimal RNA replicons characterized so far – their [▶ genome](#) is tenfold smaller than that of the smallest known virus RNA – and, therefore, they can be regarded as the frontier of life (Diener 1972; Gross et al. 1978). Despite being only composed by a small nonprotein-coding RNA molecule, viroids contain sufficient information to infect some plants, to manipulate their gene expression for producing a viroid progeny, and to incite in most cases specific diseases (Diener 2003). In contrast to viruses, which can be essentially considered as parasites of the translation machinery of their host, viroids parasitize their host [▶ transcription](#) machinery.

The approximately 30 known viroid species are grouped into two families, *Pospiviroidae* and *Avsunviroidae*, the members of which replicate and accumulate in the nucleus and the chloroplast, respectively. As opposed to viruses, which encode in their genomes proteins that mediate their replication, movement, and suppression of host defense, viroids depend exclusively on host factors for these purposes. Viroids replicate through an RNA-based rolling circle mechanism with three steps that, with some variations, operate in both polarity strands (Branch and Robertson 1984): (1) synthesis of longer-than-unit strands catalyzed by a host RNA polymerase that reiteratively transcribes the incoming circular template; (2) processing to unit length, which remarkably is mediated by hammerhead ribozymes in the family *Avsunviroidae* (Hutchins et al. 1986; Flores et al. 2000); and (3) circularization resulting from the action of an RNA ligase or from self-ligation.

Certain viroid properties, including their size, circularity, structural periodicity, and lack of protein-coding capacity and, specially, the presence of hammerhead [▶ ribozymes](#) in the family *Avsunviroidae*, support the idea that they may have a very ancient evolutionary origin

independent of viruses. In line with this view, the mutation or error rate of a hammerhead viroid is the highest reported for any biological entity (Gago et al. 2009). Viroids, which therefore propagate in their hosts as populations of closely related sequence variants ([▶ quasispecies](#)), may tolerate such elevated mutation rates owing to their small genome size (Eigen and Schuster 1977). Given their genomic simplicity and catalytic activity, hammerhead viroids are reminiscent of the postulated [▶ RNA world](#) replicons (Gilbert 1986; Diener 1989), for which an extremely error-prone replication has also been assumed. The high-error rate of precellular replication may have promoted the emergence of polyploid genomes, with the mechanism of viroid replication (reiterative transcription of a circular template) providing an efficient channel for genome duplication. Additionally, evolution of complexity in the early history of life must have entailed emergence of replication fidelity mechanisms.

Definition

Virology is the discipline of biology which studies viruses and subviral pathogens such as ► [viroids](#) and ► [prions](#). Different research areas are identified in current virology. Basic virology is interested in the structure of the viral particle and its constituents, as well as in the genetics, evolution, and taxonomy of viruses. Applied virology uses either whole viruses or parts of them – capsids, nucleic acids, or proteins of viral origin – for biotechnological or biomedical applications. Research in clinical virology includes the study of viral pathogenesis and epidemiology, as well as the development of antiviral drugs and vaccines. As a result, since the 1940s, many of the basic concepts and tools of ► [genetics](#) and molecular biology have been derived from the study of viruses and the viral replication cycle within the host cell.

Definition

“Viruses are entities whose ► [genomes](#) are elements of ► [nucleic acid](#) that replicate inside living cells using the cellular synthetic machinery and causing the synthesis of specialized elements that can transfer the viral genome to other cells” (Luria et al. 1978). Viruses are infectious obligate intracellular parasites that can enclose their nucleic acid genome in a protein capsid and persist extracellularly. Viruses can be considered “bags” of nucleic acid.

Overview

Viruses have been termed the ultimate parasite. To replicate, viruses must release their genome composed of either DNA or RNA (either single or double stranded, or in rare cases both), inside a cellular host. This release process, or infection, occurs by disassembly of the extracellular virus particle, the virion. Once inside the cell, viruses require cellular ► [translation](#), in particular the ► [ribosome](#), for viral protein production. Some viruses can replicate their genome using exclusively viral proteins, but some require cellular proteins, often including DNA or RNA polymerases. After virus genomes and proteins are made, virions are assembled in a process unique to viruses. In the absence of a host cell, viruses do not undergo ► [metabolism](#), but when inside a host, they can drastically modify host metabolism. Viruses can infect archaeal, bacterial, or eukaryotic organisms. On Earth, viruses outnumber cellular organisms by orders of magnitude and are much more genomically complex. The origin and antiquity of viruses are unclear and hotly debated (Koonin et al. [2006](#)).

Key Research Findings

History of Virology

Before the discovery of ► [bacteria](#), all infectious diseases were known as “viral,” since the Latin for poison is *virus*. Only after the introduction of filters that did not allow the passage of bacteria in the late nineteenth century were viruses discovered to be separate infectious entities. Viruses infecting bacteria, also known as bacteriophages or phages, were discovered in the early twentieth century. Until recently, viruses were always associated with disease (Luria et al. [1978](#)).

Viruses Are Everywhere

Now practically all organisms are known to have viruses, many benign; some viruses even appear to have viruses of their own (Claverie [2006](#)). Massive numbers of viruses have been discovered in all ► [ecosystems](#), including oceans (Suttle [2005](#)), soils (Srinivasiah et al. [2008](#)), and extreme

environments (Prangishvili et al. [2006](#)). The number of viruses on Earth is calculated to be an astronomical 10^{31} , with genetic diversity swamping that of cellular ► [life](#). If all of the predicted oceanic viruses were lined up end to end, they would be 50 million light-years long. Viruses play a critical role in global nutrient cycles (Suttle [2005](#)) as well as in the ► [lateral gene transfer](#) between organisms. From 8% to 40% of the human genome is viral or virus derived (Lander et al. [2001](#); Venter et al. [2001](#)). Other sequenced genomes have similar virus content (e.g., Casjens [2003](#)).

Virus Classification Is Problematic

Animal and plant viruses are named by the diseases that they cause, for example, herpesviruses, *Tobacco mosaic virus*, etc. Viruses of Bacteria and ► [Archaea](#) have abstract or descriptive names such as T4, fuselloviruses, etc. Most named viruses infect animals, fewer infect plants, and even fewer infect microbes. However, the latter is by far the largest and most diverse group. Standard virus classification is based on genome (DNA or RNA, single stranded or double stranded), shape of the virion, and whether it has a lipid envelope or membrane (Fauquet et al. [2005](#)). However, there are a number of exceptions, whereby clearly related viruses are not grouped together. Thus, other methods have been proposed. One is based on shared structures, which indicate that viruses infecting Bacteria, Archaea, and ► [Eukarya](#) have a ► [common ancestor](#) (Krupovic and Bamford [2008](#)). Attempts have been made to classify viruses based on their genome sequences, but this has not been successful mostly due to a lack of conserved genes (Hendrix et al. [1999](#)). On the other hand, viruses are often defined as “small”. The *Mimivirus*, however, is visible in the light microscope and contains a genome larger than many Bacteria and Archaea. The *Mimivirus* genome lacks a ribosomal RNA gene but contains many otherwise “cellular” genes (Raoult et al. [2004](#)). Since the late 1960s, the International Committee on Taxonomy of Viruses (ICTV) develops and maintains a universal virus ► [taxonomy](#). A recent virus genome was found that appears to have arisen by

a fusion between RNA and DNA viruses, further confusing classification (Diemer and Stedman 2012).

Applications

Starting in the 1940s, researchers led by Max Delbrück and Salvador Luria used bacterial viruses to study fundamental aspects of biology. This approach was successful beyond all expectations. These studies led to the discovery of mRNA and the conclusive determination that DNA was the genetic material, that genes are linear, that the genetic code is triplet, etc. (Cairns et al. 1992). The study of animal viruses was critical for the discovery of DNA splicing, DNA replication, ► [transcription](#), etc. The study of the archaeal virus SSV1 showed that archaeal and eukaryal transcription mechanisms are closely related (Reiter et al. 1988). Most of the advances in molecular biology and biotechnology have been derived from research on viruses. As self-assembling nanoparticles, viruses are of great interest for nanotechnology (Mao et al. 2009). They are also promising gene therapy vectors.

Future Directions

Are Viruses Alive?

Researchers and students alike debate whether viruses are alive. The question is really semantic, since it depends on the definition of ► [life](#) or what it means to be alive. Viruses evolve, replicate, mutate, persist in many environments, and are large and critical parts of extant ecosystems (Suttle 2005). On the other hand, viruses are inert when not inside a host cell, they lack metabolism, and they can be crystallized and chemically synthesized (Wimmer et al. 2009). Viruses modify organism's metabolism, even though they have none as a virion. Striking examples are viruses of marine ► [cyanobacteria](#) that reprogram their host's energy-generating photosystem (Clokic and Mann 2006). Viruses may also have been involved in some major transitions in cellular life, such as the split of Bacteria, Archaea, and

Eukarya and the development of DNA as the genetic material from an ► [RNA world](#) (Forterre and Prangishvili 2009). Research on viral ► [quasispecies](#) has shown the great adaptive potential of current RNA viruses and has provided interesting clues on possible replicative strategies during the ► [RNA world](#) (Domingo 2007).

Where Do Viruses Fit in the "Tree of Life"?

Universal molecular phylogenies depend on conserved genes, often ribosomal. Since no virus genomes found to date contain ribosomal RNA genes, analysis of these genes cannot determine viruses' relationships to cellular organisms. No genes are completely conserved in virus genomes, but a number of viral "hallmark genes" are found only in virus genomes (Koonin et al. 2006). However, many other genes in virus genomes are cellular in origin, and vice versa. Viruses are agents of lateral or horizontal gene transfer; they must release their genomes into host cells, and newly replicated virus genomes are packaged in host cells. Thereby, viruses can either acquire or deliver genes to their hosts. Therefore, it is difficult to construct molecular phylogenies for viruses. In addition, many virus genes have no known homologues, making tree construction problematic. Recent attempts to determine virus phylogeny have concentrated on structural instead of sequence similarity (Krupovic and Bamford 2008). Based on the *Mimivirus* genome, some authors have proposed that viruses are a fourth domain of life equivalent to Bacteria, Archaea, and Eukarya (Raoult et al. 2004). More recently, it was proposed that viruses should be called "capsid-encoding organisms" (CEOs) while cellular life should be called "ribosome-encoding organisms" (REOs) (Raoult and Forterre 2008). Both of these proposals are controversial (Moreira and Lopez-Garcia 2009).

Unique Viruses in Extreme Environments

Viruses from extreme environments, some of them off-Earth analog environments, are particularly interesting because their genome sequences and virion structures are unique. Viruses of thermoacidophilic Archaea are particularly striking, ranging from spindle shaped to filamentous

and longer than the host cell. Some of them have no genes in their genomes with any homologues in any other (viral or cellular) genome. Nonetheless, some of these viruses are clearly closely related. Even though some of them have lipid membranes, others do not, contradicting one major tenet of virus classification (Prangishvili et al. 2006). The thermoacidophile virus STIV may provide a “missing link” between viruses infecting Bacteria, Eukarya, and Archaea (Hendrix 2004).

Antiquity of Viruses?

How old viruses are is an open question. There are no reported viruses in the rock record, but work is ongoing to determine if virus biosignatures can be preserved. “Paleoviruses” have been reconstructed and indicate that some current human retroviruses are at least 44 million years old (Emerman and Malik 2010). The oldest direct indication of viruses is the particles observed in ca. 100-million-year-old amber inclusions (Poinar and Poinar 2005).

Indirect evidence from the study of virion protein structures in bacterial, archaeal, and eukaryal viruses indicates a common viral ancestor present at the split of the three host lineages, billions of years ago (Hendrix 2004). Some have proposed that the eukaryotic nucleus is derived from a virus (Claverie 2006). Based on molecular phylogeny, the lack of cellular homologues to many virus genes and that some viruses use RNA as their genetic material, Eugene Koonin and colleagues have postulated that viruses predated cellular life and are a remnant of the RNA world (Koonin et al. 2006). Again, some of these ideas have been rejected by other researchers (Moreira and Lopez-Garcia 2009).

Viruses Relevance for Astrobiology

On Earth, viruses outnumber all other organisms by orders of magnitude. If an extraterrestrial were to collect a “representative” sample from Earth, seawater, there would be far more viruses in that sample than any other biomarkers. Viruses also require a cellular host to replicate; thus, if viruses or biomarkers thereof are found on other planets, this would strongly indicate the presence of

cellular life. Viruses are clearly involved in lateral gene transfer; this is how they replicate. Lateral gene transfer appears to have been critical in the evolution of life on Earth. If viruses are remnants of the RNA world and may even have predated cellular life, it is critical to study them to understand this fundamental stage in the development of life on Earth and possibly beyond.

Viscosity

Avi M. Mandell
NASA Goddard Space Flight Center, Greenbelt,
MD, USA

Definition

Viscosity is the physical parameter that describes the resistance of any medium in general and of astrophysical fluids in particular to shear stress. In a ► [protoplanetary disk](#), the stress can be caused by differential orbital velocity of material. Viscosity in a protoplanetary disk causes the gaseous component of the disk (the bulk of the mass in a primordial disk) to lose gravitational energy to heat, causing the material to heat up (known as “viscous heating”) and causing orbital decay and infall of material onto the central star (known as “viscous accretion”). Viscosity in astrophysical fluids can be generated by a number of different mechanisms (i.e., molecular viscosity, magnetorotational instability), and the type and magnitude of the viscosity in protoplanetary disks are unknown, but observations of gas accretion onto young stars support the existence of viscosity which is larger than the molecular one.

Viscous Stirring

Rory Barnes
Astronomy Department, University of
Washington, Seattle, WA, USA

Definition

In planet formation theory, viscous stirring corresponds to the transfer of orbital energy of a single particle into kinetic energy of other particles. For example, a large particle (relative to the typical-sized particle) in a ► [protoplanetary disk](#) can increase the velocity of a smaller body as it passes by due to its stronger gravity. When this acceleration occurs, the larger particle transfers a fraction of its energy to the smaller object. This situation is not to be confused with ► [dynamical friction](#), in which the random motion of the large particle decreases as a result of the excess of particles focused behind it.

Synonyms

[VIS](#); [Visible](#)

Definition

The term visible designates the domain of electromagnetic waves that is perceptible to the human eye. The response of an average human eye is between the wavelengths 390 nm (limit of ultraviolet) and 750 nm (limit of infrared). Until the mid-twentieth century and the advent of radio astronomy and of the spaceborne instrumentation for the gamma-ray, X-ray, UV, and infrared domains, observing in the visible was the unique way for astronomers to get information on the universe. The domain is often abbreviated by the term VIS. The photometric filter V at 550 nm stands for visible.

Toulouse Jean-Jaurès, Toulouse, France

Keywords

Life · Materialism · Medicine · Ontology ·
Organism

Synonyms

[Holism](#); [Organicism](#)

Definition

Vitalism is typically presented as the belief – scientific, metaphysical, poetic, and other – in the uniqueness of life, presented as a “substance,” “force,” or “principle.” As such, it is a frequently

criticized theory, often in caricatural forms, where a model of organism, embryo development, or forms of nonmechanical causality, is called “vitalist” – a label applied to various theories which have little in common with each other, with entirely different empirical bases and/or metaphysical commitments. In fact, the historical and conceptual significance of the category of vitalism for biological thought lies in its perpetual challenge to justify the autonomy of biological entities.

Overview

In a recent review of the status of theoretical biology, we are told that “in vitalism, living matter is ontologically greater than the sum of its parts because of some life force (‘entelechy,’ ‘élan vital,’ ‘vis essentialis,’ etc.) which is added to or infused into the chemical parts” (Gilbert and Sarkar 2000). As such, it is also usually opposed to ► [materialism](#), which is often understood as a strictly “mechanistic” and/or physicalistic account of matter. While this is a correct description of ideas dating back to the late nineteenth century, particularly the vitalism put forth by the embryologist Hans Driesch, it is incorrect about vitalism in general. Driesch derived from experiments on sea urchin embryos a metaphysical theory of what he called “entelechies,” entities which somehow existed apart from the causal, space-time world studied by natural science (Driesch 1914). In contrast, eighteenth-century vitalism, notably as defined and practiced by physicians such as Bordeu, Ménuret de Chambaud, and Barthez at the Montpellier Faculty of Medicine (where the word is first used to describe a medical doctrine), is not a metaphysical claim about a mysterious life force (Cimino and Duchesneau 1997; Rey 2000; Williams 2003). It is a more practical, heuristically oriented medical and philosophical program that uses functional, Newtonian-inspired models of organism to discuss temporal, dynamic, and sometimes subjective dimensions of embodiment – disease, crisis, pulse, nosology, etc. (Wolfe 2008). In addition, Montpellier vitalism is “materialism friendly,” denying the existence of the soul

other than as an organic entity, and believing that higher functions are explainable in terms of arrangements of living matter – as one can also see with the vitalist Bordeu’s inclusion as a (positively presented) character in Diderot’s philosophical novel *D’Alembert’s Dream* (1769). It is important to distinguish between this earlier, medically based vitalism and a later, more metaphysically oriented vitalism, even if the latter begins with embryological (developmentalist) work. In addition to these two forms of vitalism – *ontological* (Driesch) and *functional* (the Montpellier School) – in the twentieth century, thinkers such as Kurt Goldstein and Georges Canguilhem developed a *projective* or *attitudinal* vitalism, in which it is presented as an *attitude* living beings necessarily adopt toward other such beings (Goldstein 1934/1995; Canguilhem 1965/2008; Wolfe 2011; Huneman and Wolfe 2010). It is interesting to observe that has been termed here “functional vitalism” is quite hard to distinguish from twentieth- (and twenty-first) century organicism, inasmuch as it is less a metaphysically founded set of claims about the uniqueness of biological entities and more an attempt to describe their uniquely relevant “systemic” functional properties (an approach that is very well articulated in Claude Bernard’s approach to what he called “organic machines”: Canguilhem 1989). In that sense, vitalism, or the “problem of vitalism,” directly interrogates the status quo of a kind of back-and-forth between reductionist and anti-reductionist approaches, and not necessarily as the most extreme anti-reductionist view (Chen 2018). In sum, vitalism comes in different forms, some of which seem well beyond the pale for mainstream biological thought, others which can serve as useful heuristics or correctives in attempting to deal with the question of the ontological status of living entities (Normandin and Wolfe 2013, Wolfe 2019, 2020, 2021).

VLBI

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Synonyms

[Very Long Baseline Interferometry](#)

Definition

Very Long Baseline Interferometry (VLBI) is a variant of the radio interferometry technique currently used in astronomy, but combining the signals of extremely distant telescopes. VLBI provides observations of an object with an exquisite angular resolution, equivalent to that of a telescope whose size is the separation between the distant telescopes. This distance can reach thousands of km (transcontinental VLBI), thus allowing measurement of details as small as 10 milli-arcsec (mas), i.e., one hundred times finer than with a conventional telescope in visible light. To achieve VLBI observations, the radio signal is locally recorded together with time stamps of an atomic clock and later the different data from all antennas are correlated using digital electronics and computers to produce the resulting image.

Very Large Telescope

Definition

The Very Large Telescope (VLT) is the main facility for European ground-based optical astronomy. It consists of four Unit Telescopes (UTs) with primary mirrors of 8.2-m diameter and four movable 1.8-m-diameter ► [telescopes](#), situated in the north of Chile. It features a very complete suite of instruments, large-field imagers, ► [adaptive optics](#)-corrected cameras and spectrographs, as well as high-resolution and multi-object spectrographs, and the VLT covers a broad spectral region, from ultraviolet (300-nm) to mid-infrared (24- μ m) wavelengths. It is also able to work in recombined or interferometric mode. This is the world's most important facility for visible/infrared astronomy.

Overview

The Very Large Telescope array (VLT) is operated by an international organization, the European Southern Observatory (ESO). Located on Cerro Paranal in Northern Chile (70° 24' 11" W; 24° 37' 31" S) at an altitude of 2635 m, it operates at wavelengths ranging from 0.3 to 25 μ m. It is the world's largest optical instrument, consisting of four Unit Telescopes with main mirrors of 8.2-m diameter and four movable 1.8-m-diameter telescopes (Auxiliary Telescopes: see Fig. 1), able to

work in a collaborative way (interferometric mode). The first of the Unit Telescopes, "Antu," was commissioned on April 1, 1999. Today, all four Unit Telescopes and all four Auxiliary Telescopes (ATs) are operational.

The telescopes can be optically linked when working in the interferometric mode (VLTI), or the 8.2-m-diameter Unit Telescopes can be used individually.

The 8.2-m-diameter telescopes are housed in compact, thermally controlled buildings, which rotate synchronously with the telescopes, thus limiting the disturbing effects of air turbulence in the telescope tube. The VLT Unit Telescope has an altazimuth mount. In such a mount, the telescope tube moves around a horizontal axis (the elevation axis), and the two bearings that support the tube are mounted on a fork rotating around a vertical axis (the azimuth axis), thus enabling the telescope to point over the entire sky.

The VLT Unit Telescope optical layout is of the Ritchey-Chrétien type. Each of the four ► [telescopes](#) can operate in either Cassegrain, Nasmyth, or coudé focus. The light is collected by the primary mirror (M1) and then concentrated by the combination of the primary and the secondary mirror (M2), either directly to the Cassegrain focus located below the primary or to one of the two Nasmyth foci. The coudé focus is obtained by transferring one Nasmyth focus to another location in the telescope basement by means of an optical relay system. From the coudé focus, the light is sent to the interferometric focus. Due to the low ratio between their thickness and diameter, the VLT monolithic primary mirrors are rather flexible, thus requiring permanent control of their optical shape through active optics. This consists in applying controlled forces to the primary mirror and in moving the secondary mirror in order to cancel out the optical errors. The system essentially compensates for static or slowly varying deformations such as thermal effects, low frequency components of wind buffeting, and gravitational deformation due to telescope inclination.

The four 8.2-m Unit Telescopes are mostly used for individual observations, thanks to an ambitious instrumentation program. It includes

VLT, Fig. 1 A view of the Very Large Telescope (VLT) at night. One can see three smaller Auxiliary Telescopes in the foreground and the four enclosures of the large Unit Telescopes

large-field imagers, ► [adaptive optics](#)-corrected cameras and spectrographs, as well as high-resolution and multi-object spectrographs and covers a broad spectral region, from ultraviolet (300-nm) to mid-infrared (24- μm) wavelengths. The suite of instruments is as follows (Fig. 2):

- FORS1 and FORS2 (FOcal Reducer and low dispersion Spectrograph) are a visible light camera and multi-object spectrograph with a 6.8-arcmin field of view.
- ISAAC (Infrared Spectrometer And Array Camera) is a near-infrared imager and spectrograph.
- UVES (Ultraviolet and Visual Echelle Spectrograph) is an ultraviolet and visible light spectrograph.
- FLAMES (Fibre Large Area Multi-Element Spectrograph) is a multi-object fiber feed unit for UVES and GIRAFFE, the latter allowing simultaneous ► [spectroscopy](#) of a 100 objects at moderate spectral resolution in the visible.
- NACO (NAOS-CONICA, NAOS meaning Nasmyth Adaptive Optics System and CONICA meaning COudé Near-Infrared CAmera) is an ► [adaptive optics](#) facility, which produces infrared images as sharp as if taken in space and includes spectroscopic, polarimetric, and coronagraphic capabilities.
- VISIR (VLT spectrometer and imager for the mid-infrared) provides diffraction-limited ► [imaging](#) and ► [spectroscopy](#) at a range of resolutions in the 10- and 20- μm mid-infrared (MIR) atmospheric windows.
- SINFONI is a medium resolution, near-infrared (1–2.5- μm) integral field spectrograph fed by an adaptive optics module.
- CRILES (CRYogenic InfraRed Echelle Spectrograph) is adaptive optics assisted and provides a resolving power of up to 100,000 in the infrared spectral range from 1 to 5 μm .
- HAWK-I (High-Acuity Wide-field K-band Imager) is a near-infrared imager with a relatively large field of view.
- VIMOS (VISible Multi-Object Spectrograph) delivers visible images and spectra of up to 1000 galaxies at a time in a 14×14 -arcmin field of view.
- X-Shooter, the first second-generation instrument, a wide-band [UV to near infrared]

VLT, Fig. 2 The four Unit Telescopes (*UTs*) and the four Auxiliary Telescopes (*ATs*) that form the VLT. The various instruments available at the different foci are indicated

► **spectrometer** designed to explore the properties of rare, unusual, or unidentified sources.

The telescopes can also work together, in groups of two or three or even more, to form a giant “interferometer,” the ESO Very Large Telescope Interferometer, allowing astronomers to capture details up to 25 times finer than with the individual telescopes. The light beams are combined in the VLTI using a complex system of mirrors in underground tunnels where the light paths must be kept equal to distances less than 1 μm over 100 m. The VLTI can reconstruct images with an angular resolution of milliarcseconds.

The 8-m UTs are used for interferometric observations for a limited number of nights every year, but four smaller, dedicated, Auxiliary Telescopes (ATs) are available to allow the VLTI to observe interferometrically every night. The ATs are mounted on tracks and can be moved between precisely defined observing positions from where the beams of collected light are combined in the VLTI. The ATs are dedicated ► **telescopes**, self-contained in their ultracompact protective domes,

and travel with their own electronics, ventilation, hydraulics, and cooling systems. Each AT has a transporter that lifts the ► **telescope** and moves it from one position to the other.

The VLT is the most productive individual ground-based facility in the world, and results from the VLT have led to the publication of an average of more than one peer-reviewed scientific paper per day.

Volatile

Henderson James Cleaves
Earth-Life Science Institute (ELSI), Tokyo
Institute of Technology, Tokyo, Japan
Blue Marble Space Institute of Science,
Washington, DC, USA
Georgia Institute of Technology, Center for
Chemical Evolution, Atlanta, GA, USA

Definition

In planetary science, volatiles are chemical elements and compounds with low boiling points typically associated with a planet's or Moon's crust and/or atmosphere. Some examples include nitrogen (N or N₂), water, carbon dioxide, ammonia, hydrogen (H or H₂), methane, and sulfur dioxide. These compounds or elements, in the solid state, are often significant components of the crusts of moons and planets. Planetary scientists often classify volatiles with exceptionally low melting points, such as hydrogen and helium, as gases, while those volatiles with melting points above about 100 K are classified as ices. Here, the terms “gas” and “ice” can be applied to compounds that may be solids, liquids, or gases. Thus, Jupiter and Saturn are referred to as “gas giants,” and Uranus and Neptune are referred to as “ice giants,” even though the majority of the “gas” and “ice” in their interiors is liquid. The Earth's Moon has a very low volatile content. Its crust contains oxygen chemically bound in the rocks, but negligible amounts of H, N, or C. In contrast, those elements and compounds with high boiling points are known as refractory substances.

Scientists working on planetary interiors apply the term volatile to elements that are gaseous at magnetic temperatures (>1300 K). Typical

volatiles are gases such as H₂O, CO₂, CH₄, but also Hg, Zn, Pb, S, and alkali elements.

Volcaniclastic Sediment

Nicholas Arndt
Emeritus Professor, ISTerre, University Grenoble
Alpes, Grenoble, France

Definition

A *volcaniclastic sediment* is a sediment (regardless of the average grain or clast size) composed primarily of debris of effusive ► [igneous rocks](#) (volcanic material). This volcanic material may be pyroclastic (fragments derived from explosive volcanism) or hyaloclastic (fragments formed by thermal shock when hot lava comes in contact with cool sea or lake water). Undisturbed clastic deposits of volcanic materials are called volcanoclastic; the term sediment is added when the material has been reworked and redeposited by water, wind, or gravity. Volcaniclastic sediments have a wide range of compositions, from ► [basalt](#) (rarely ► [komatiite](#)) to rhyolite. They may display sedimentary features familiar from siliciclastic sediments, such as graded or cross bedding (i.e., cross-stratification, when layering is produced within a sediment stratum and with an angle respect to the main bedding plane). Commonly, volcanoclastic sediment undergoes metasomatism or diagenetic changes, including carbonatization or silicification, for example, by hydrothermal fluids.

Volcano, Planetary

Daniele L. Pinti

GEOTOP Research Center for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Definition

Volcanoes are structures (constructional volcano edifices) created by the accumulation of erupted molten lava or solid, fragmental pyroclastic rocks (or pyroclasts). Volcanoes range in size from small cones a few tens of meters high to enormous shields hundreds of km in diameter. Most volcanoes on Earth and other planets are cone shaped. The morphology of the volcano edifice depends basically on the type of volcanic material which erupted. When the lava is relatively fluid, such as ► [basalt](#), volcanic edifice has low-angle slopes creating a so-called ► [shield](#) volcano. When the lava consists of very viscous rhyolite, the extrusion of pasty lava tends to form a dome, or the explosive eruption of the highly viscous material and fragmental material will form a steep-sided structure called stratovolcano. Volcanoes are commonly present on Earth as a result of ► [plate tectonics](#) processes and on other telluric planets of our Solar system, namely Mars and Venus, and on Jupiter moon Io. Constructional volcano edifices can be also be produced by eruption of glaciated material (cryovolcanism on Titan and Enceladus moons) or eruptions of mud (mud volcanism on Earth and possibly on Mars).

Overview

Volcanoes are the superficial expression of planetary tectonics. On Earth, volcanoes are mainly distributed along convergent margins of tectonic plates, where they form insular (i.e., Japan) or continental (i.e., Andes) arcs and at the apex of mantle plumes (i.e., Hawaii or Tahiti). At convergent margins, hydrated sediments are subducted together with the basaltic seafloor back to the mantle. Dehydration of the subducting sediments and incorporation of water at the mantle wedge (i.e., the triangular-shaped region of mantle which lies above the subducting plate and below the overriding plate) lowers the mantle melting point allowing magmas to form and to reach the surface. The occurrence of water and associated volatiles and the relative high viscosity of the formed magmas (from andesitic to rhyolitic in composition) provoke at the surface the phenomenon of *magma fragmentation*. *Magma fragmentation* is the breakup of molten rock into discrete pieces, called pyroclasts. Magma contains bubbles of compressible magmatic volatiles. If the magma is highly viscous, resistance to bubble growth will instead lead to excess gas pressure and the magma will deform viscoelastically by fracturing like a glassy solid, resulting in the formation of a violently expanding gas-pyroclast mixture, which provokes explosive eruptions (Gonnermann 2015). Volcanic chains as Hawaii are the surface expression of a mantle plume rising from the core-mantle boundary or from the bottom of the ► [asthenosphere](#). Magmas are generally low in viscosity (basalts). In this case, gas bubbles can expand freely, and the eruption is reduced to lava flows, or, in case of high gas content, to lava fountains. The type and nature of erupted material control the morphology of volcanoes, with large shield volcanoes produced by low-viscosity lava flows and stratovolcanoes from alternances of pyroclastic material and lavas. Yet the morphology can be further complicated by the migration of the position of the erupting vent with time, creating complex nested edifices (typical is the Colima stratovolcano in Mexico; the Piton des Neiges-Piton de la Fournaise in Reunion Island,

or the Somma-Vesuvius, Italy). Secondary processes related to partial emptying of the magma chamber beneath a volcano edifice or lateral eruptions can create partial collapses of the edifice (Mt. St Helens in 1980). During cataclysmic eruptions, the complete emptying of the magma chamber brings to the total collapse of the edifice with the creation of a typical caldera, a large cauldron-like hollow (Yellowstone is the most known).

The presence of volcanoes usually indicates magmatism, the opposite is not always true. Indeed, the largest volume of magma on Earth (80% of the total) is erupted at the ► [mid-ocean ridges](#), where oceanic crust is formed, and the majority of volcanic material is emitted through fractures (fissural volcanism). Accumulating basaltic flow along the mid-ocean ridges create long “mountainous” chains but no single constructional volcano edifices. On Earth, fissural volcanism is also responsible for the continental flood basalts (CFB) or ► [Trapps](#) which are characterized by voluminous step-like basaltic sequences (Trapps means “stairs”). This is also the case on other telluric planets of the Solar system. For example, Mercury is covered by a volcanic crust, and numerous are the evidence of lava flows, but not indication of constructional volcanic edifices (Wright et al. 2018), except for 11 volcanic domes detected on its surface. It is likely that most of the past volcanic activity of Mercury was related to fissural volcanism. Venus, Mars, the Moon, and Jupiter’s satellite Io show volcanic edifices. Venus shows numerous volcanic structures and the highest density of volcanoes of any other planet or moon in the Solar system (around 1000). They are mainly shield volcanoes (such as the 8 km height Maat Mons) indicating emission of low viscosity molten rocks such as those emitted by the Hawaiian hot spot volcanoes. High thermal emissions detected by the Venus Express spacecraft suggest that volcanic activity could be recent, less than 2.5 Ma ago (Smrekar et al. 2010). The Moon has volcanoes typically in the form of small domes and cones that form large volcanic complexes and isolated edifices. Calderas are exceptionally rare. Volcanism was active from 4.2 to 1.2 Ga ago, though new volcanic

features discovered in the far side of the Moon suggest more recent limited volcanic activity not older than 50 Ma (Watters et al. 2012). Mars is dominated by the largest volcanoes on the Solar system, mainly shield volcanoes as those concentrated in the Tharsis Volcanic Province (Ascraeus Mons, Pavonis Mons, and Arsia Mons collectively named as Tharsis Montes). These three huge shield volcanoes are aligned NE-SW. Off axis, on the NW of the Tharsis Montes there is the highest shield volcano of the Solar system, Olympus Mons (21 km above Martian datum with 4–5° slopes for a 71 x 92 km diameter). In addition to the large shield volcanoes, Tharsis region contains smaller volcanoes called *tholi* and *paterae*. *Tholi* are dome-shaped edifices with flanks that are much steeper than the larger shield volcanoes. Their central calderas are also quite large in proportion to their base diameters. *Paterae* (a Latin word indicating a shallow drinking bowl) appears to be morphologically like the *tholi*, except for having larger calderas. It is believed that these two structures represent the summit of buried larger shield volcanoes. The volcanic activity on Mars was mainly concentrated between the Noachian (3.7 Ga ago) and Amazonian (500 Ma ago) though there are speculation that much recent volcanic activity resurfaced some areas of the Tharsis region (Hauber et al. 2011). The fifth moon of Jupiter, Io, has the largest volcanic activity among the planetary bodies of the solar system. The surface is splotched with lava lakes and floodplains of molten lava, and 150 active volcanoes have been detected, but the total number could reach more than 400. Volcanic activity is accompanied by sulfur and sulfur dioxide plumes that can reach 300 km altitude in the Io’s atmosphere.

Constructional volcanic edifices are not only produced by emission of molten rock but by other fluids such as mud and ice (Hargitai et al. 2014). Mud volcanism is the extrusion at the surface of Earth of mud and water driven by gases such as methane in hydrocarbon-bearing basins (Mazzini and Etiope 2017). These extrusions normally create relatively small, pitted cones and mounds but in Pakistan the largest ones can reach 100 m in

diameter and up to 700 m height. Pitted cones and mounds at the surface of Mars could be derived by mud volcanism (Skinner Jr and Mazzini 2009). Cryovolcanism, namely “the extrusion of liquids and vapors of materials that would be frozen solid at the planetary surface temperatures of the icy bodies of the outer solar system” (cf. Geissler 2015), is believed to produce constructional volcanic edifices, particularly on Saturn’s moon Titan (Doom Mons). The majority of cryovolcanic activity observed in the Solar system, particularly on Saturn’s moon Enceladus, is limited to geysers.

Vortex, Vortices

Sean N. Raymond
 Laboratoire d’Astrophysique de Bordeaux,
 CNRS, Université de Bordeaux, Bordeaux,
 France

Definition

In the context of gaseous protoplanetary disks, vortices are spinning regions that undergo anticyclonic rotation. The existence and longevity of vortices in planet-forming disks is still debated. If vortices do exist, they could accelerate the process of planet formation by providing regions where solids are accumulated, which would speed up the process of planetesimal growth.

Subglacial Antarctic Lake Vostok

Definition

The subglacial Lake Vostok (Russian, “east”) is the largest, deepest, and most studied lake among more than 400 subglacial lakes (water features) inventoried through airborne radio-echo sounding and satellite altimetry surveys (Siegert et al. 2016; Wright and Siegert 2012). It is located beneath the Russian Vostok Antarctic research station, and it has already been unsealed in triple (Bulat 2016). The naturally refrozen lake water, or accretion, ice collected by deep drilling and used as a proxy for the lake water has proved to be exceptionally clean, though much diluted, leading to controversial biological and chemical analyses. Nevertheless, the likely indigenous DNA fingerprint of a chemolithoautotrophic thermophile along with some other bacteria seems to fit with the lake’s extreme environment.

Overview

Subglacial lakes are water bodies formed at the base of the 3–4 km thick Antarctic ice sheet due to the geothermal heat flux, which melts basal ice layers. The meltwater accumulates in bedrock troughs with long residence times (Bell et al. 2002). It may be periodically discharged through a subglacial hydrologic network (Wingham et al. 2006), depending on geological and bedrock relief settings.

The subglacial Lake Vostok was discovered by radio-echo sounding in the late 1960s (Oswald and Robin 1973). It was mapped in detail by radar altimetry in the 1990s (Ridley et al. 1993) and defined as a lake after seismic ground studies in 1996 (Kapitsa et al. 1996). It is the largest and deepest subglacial lake located beneath the Vostok station (78° S, 106° E, elevation 3488 m, ~1300 km from the coast, mean surface annual temperature -55.1°C) under the ~3750–4200 m thick central East Antarctic ice sheet (Fig. 1).

The subglacial Lake Vostok is the best-studied water feature in Antarctica (Petit et al. 2005). It is crescent-shaped and extends northward from Vostok station for more than 275 km in a deep trough and has a surface area of $\sim 15,000\text{ km}^2$, similar to that of Lake Ontario in North America. It is 65 km wide and $\sim 400\text{ m}$ deep on average with a volume of $\sim 6100\text{ km}^3$ (Popov et al. 2011). There are two separate basins, one with a trough as deep as 1650 m in the southern region (Masolov et al. 2001, 2006; Studinger et al. 2003). Lake Vostok is a tectonically controlled subglacial lake with minor recently recorded tectonic activity (Studinger et al. 2003). The lake has likely been isolated from the surface for ~ 14 million years, the time of the major East Antarctica glaciation (Bo et al. 2009).

The overlaying glacier flows at $\sim 2\text{ m/year}$ across the lake. From the South (Vostok region) to the North, the ice thickness increases from 3750 to 4200 m because of the deepening bedrock trough. This imposes a tilted interface between the lacustrine water and the overlying ice. As the melting point changes with pressure, the glacier’s base melts on the thick side (Northern region) supplying the lake. Water also refreezes in the upper layers of the lake in the Southern region, and the so-called *accretion ice* is exported by the glacier’s movement out of the lake. This leads to the replacement of the lake water every $\sim 40\text{--}80\text{ ka}$ (Bell et al. 2002; Petit et al. 2005).

The subglacial lake environment is characterized by high pressure ($\sim 400\text{ bars}$) and in situ temperatures close to the freezing point of water ($\sim -2.6^{\circ}\text{C}$). Energy resources are seriously limited as there is complete darkness and an ultralow dissolved organic carbon content ($\text{DOC} \leq 0.010\text{ mg/L C/L}$) (Preunkert et al. 2011). The lake water is likely highly saturated with air, particularly molecular oxygen, released over long periods from the continuous ice melting (upper limit 815–1300 mg/L for dissolved O_2 concentration) (Lipenkov and Istomin 2001; Lipenkov et al. 2016; McKay et al. 2003). The accretion ice is also enriched in radiogenic ^4He originating from the bedrock and degassed through deep faults (Petit et al. 2005; Jean-Baptiste et al. 2018).

The accretion ice is composed of two distinct layers: the uppermost ice (from 3539 to 3608 m)

Vostok, Subglacial Lake, Fig. 1 The subglacial Lake Vostok as seen from space by ice-penetrating radar (RADARSAT, <http://svs.gsfc.nasa.gov/vis/a000000/a000900/a000996/>).

The Russian Vostok station location (tiny white dot, most left) and tractor traverse track (tiny white thread) were recorded as well

containing millimeter size mica-clay inclusions (accretion ice I) and the deeper ice (below 3608 m), which is transparent and very clean (accretion ice II). Various groups have studied the biological content of accretion ice samples. The nature of the samples, the integrity of microbes, the possibility of contamination from the drilling and recovery process, the introduction of nonindigenous materials, and the sparse microbial populations all suggest that caution should be taken when interpreting the results. Not unexpectedly, these limitations have led to differing opinions and, in some cases, contradictory results (Priscu et al. 1999; Christner et al. 2006 vs. Bulat et al. 2004). For example, measured microbial populations in ice range from thousands of cells per ml (up to 36,000, Priscu et al. 1999; Christner et al. 2006; Abyzov et al. 2001) to only a few (1–10) cells/mL (Bulat et al. 2004, 2009). Such a significant variation (three orders of magnitude) may be caused by differences in methodology used to decontaminate, retrieve, and process the samples. Some microbes may originate from external contamination during ice coring with drilling fluids (Alekhina et al. 2007).

From the recent studies, for which chemical and biological contamination is better documented and controlled, the Lake Vostok ice appears very clean and much diluted with respect to chemical and biological content. The lake water (at least the uppermost layer) appears almost entirely lifeless. Only a few bacterial phylotypes were identified in accretion ice, which were not related to contamination (Bulat et al. 2004, 2009; Bulat 2016). The confidently recorded DNA fingerprint

of the chemolithoautotrophic thermophile *Hydrogenophilus thermoluteolus* suggests the presence of a deep biosphere within the bedrock (Bulat et al. 2004; Petit et al. 2005; Lavire et al. 2006), while the expected high oxygen stress of the water may be very restrictive for biology (Bulat et al. 2004).

Basic Methodology

Stringent decontamination procedures have to be applied in order to remove the outer part of the ice core contaminated by heavy drilling operations with kerosene-based drilling fluid. The protocol consists of scraping off the outer surface, washing off the kerosene with special solutions followed by ozone treatment, and a series of washes with ultra-pure low-DOC content water in certified cleanroom conditions. The chemical composition of the ice has first to meet the reference profiles imposed by clean working conditions. Microscopic observations, flow cytometry assays, and culturing trials were implemented to assay the biomass. Finally, DNA-based techniques including very sensitive DNA amplifications were applied. To validate the DNA results, a contaminant library was established (Bulat et al. 2004; Bulat 2016).

Key Research Findings

Life in Lake Vostok

Referring to Bulat et al.'s (2009) data, cell concentrations would not exceed 19–24 cells/mL in

both accretion and glacial ice, respectively, values comparable to those found in other works (D'Elia et al. 2008). The chemical content is very low in accretion ice II (less than 100 mg/L for total ions), suggesting the lake is poorly saline ($<0.1\%$ taking into account ion partitioning during freezing). At the same time, sulfate salts (gypsum) and carbonates are likely to present (up to 1 g/L) within the mineral inclusions in accretion ice I (De Angelis et al. 2004). Dissolved organic carbon (DOC) is present in less than 0.010 mg C/L imposing ultra-oligotrophic conditions (Preunkert et al. 2011). The accretion ice has a total gas volume content two to three orders of magnitude lower than the glacier ice, imposing anaerobic conditions. No light is available for photosynthesis.

The overall environmental conditions in the lake and accreted ice would restrict any possible biota to chemoautotrophs. Possible redox couples seem to be limited to hydrogen and/or sulfides as electron donors and sulfates and oxygen (in sediment inclusions) as electron acceptors. The carbon dioxide or carbonate from sediments could serve as a carbon source. Therefore, if life is present, one may expect to discover anaerobic chemoautotrophic piezophilic psychrophiles in accretion ice as a special habitat and the same forms, but with a high oxygen tolerance in the lake water which is highly likely supersaturated with oxygen.

Sequencing microbial 16S rRNA genes, constrained by numerous contaminant controls and criteria, showed that the accretion ice is essentially free of microbial DNA. Bulat et al. (2004) and Lavire et al. (2006) have recorded the only confidently identified DNA signature in accretion ice of the ► [chemolithoautotroph](#) thermophile *Hydrogenophilus thermoluteolus*. The niche for this thermophile was suggested to be within deep faults of the bedrock encircling the lake (Fig. 2), where the environmental conditions of warm, anoxic, CO₂-rich sediments along with probable hydrogen emission due to water radiolysis would support this type of organism. Sporadic seismotectonic activity (Staudinger et al. 2003) might have flushed some material from the veins into the lake and the accretion ice

I (Bulat et al. 2004; Petit et al. 2005). Despite the Lake Vostok was unsealed in a triple, the water has not yet been cleanly sampled for the study. However, it is expected that the main water body of the lake could be microbe-free or contain unusual “oxygenophilic” (“extraterrestrial”) life forms.

Excepting the thermophile discovered in natural accretion ice, the present-day bacterial finds (passed all possible contamination precautions) in lake water poured into the borehole following lake unsealing (dubbed “technogenic,” i.e., contaminated lake water) include hitherto-unknown and phylogenetically unclassified phylotype w123-10 likely belonging to *Parcubacteria* Candidatus *Adlerbacteria*, the phylotype 3429v3-4 showing below genus-level similarity with *Herminiimonas glaciei* of *Oxalobacteraceae* (*Beta-Proteobacteria*) and 3698v46-27 being conspecific with several species of *Marinilactobacillus* of *Carnobacteriaceae* (*Firmicutes*). The fourth recently discovered phylotype 3721v34-24 has remained taxonomically unidentified – 87.7% (below family-level) similarity with *Mucilaginibacter daejeonensis* NR_041505 of *Bacteroidetes* (*Sphingobacteriaceae*) (Bulat et al. 2020).

Applications

Since the subglacial Lake Vostok may be viewed as the only extremely clean (microbe-free) giant aquatic system on the Earth, it provides a unique test area for searching for life on icy worlds such as Jupiter's moon Europa or Saturn's moon Enceladus. Confirmation of life living in Lake Vostok would strengthen the prospect for the possible presence of life on icy moons and planets.

Future Directions

Explorations of Antarctic subglacial lakes are entering an active phase with variable technological completion depending on the ice thickness to penetrate before reaching the water body. For lakes buried under more than 3000 m of ice, two

Vostok, Subglacial Lake, Fig. 2 Sketch of the glacier and lake basement along the Vostok ice flow line. The rock basement is represented by escarpments where deep faults allow water to seep in-depth and circulate. Fault activity and radiogenic ^4He degassing from the rocks are depicted

by a symbol of explosion and vertical arrows, respectively. A sketch of down core ^4He concentration suggests ^4He contribution from shallow depth area upstream Vostok. On the top right is shown a sediment inclusion within the ice at 3608 m depth. (Modified from Bulat et al. 2004)

major Subglacial Antarctic Environments (SAE) programs are established and ready-to-implement: Subglacial Lake Vostok (Russia) (partly done) and Subglacial Lake Ellsworth (UK) (suspended due to technological failure). In the Ross Ice shelf region (ice streams), shallow lakes (a few dozen meters under a thousand meters of ice) have been successfully reached by using a hot water system – the Lake Whillans (Mikucki et al. 2016) and the Lake Mercer (Priscu et al. 2021). Because individual lakes may have different origins and geological histories, the limnological conditions, the age, the source of founder microbes, the time of isolation, and the populations of extant microbes, if they exist, may vary from location to location. Thus, the findings in Lake Vostok will not necessarily be typical of other lakes and stream sediments like it came up with the Lake Whillans and the Lake Mercer (Mikucki et al. 2016; Priscu et al. 2021).

The subglacial Lake Vostok is a unique reservoir of genetic material evolving in cold darkness under high oxygen stress isolated from another biota for the last 14 million years and may contain organisms with distinctive adaptations. As for the Lake Vostok program, the first entry into the lake was performed at the depth of 3769.3 m on February 05, 2012. The water rose into the borehole up to 363 m and froze. During the following season, 2012–2013, drillers re-cored the fast-frozen lake water and obtained only 32 m of the ice core. Further drilling operations of re-coring this frozen lake water have been biased from the old borehole and went out into the pristine glacial ice. The second entry into the lake occurred at a depth of 3769.15 m 3 years later, on January 25, 2015. The water rose again into the borehole to the level of about 70 m and was left to freeze. In four days, drillers re-cored the icy “cork” and obtained about 12 m of a new fast-frozen lake

water core before the water came up again into the borehole and finally froze at the level of 65–67 m above the ice/water interface. However, although the Russians were the first to enter a subglacial Antarctic lake at such a great depth (3769 m) and were able to perform the lake entry twice, the drilling technology used (electromechanical drill along with kerosene drilling fluid with the use of foranes as densifier) proved to be inappropriate to collect the liquid water in general and clean samples in particular. More technological developments are needed to face such a challenge including the development of sophisticated systems consisting of well-sealed transport module preventing the contamination of in-module-encapsulated devices/samplers with the drilling fluid as well as the use of thermal drill just before the next lake unsealing.

Innovaxiom, Paris, CX, France

Synonyms

[Voyager 1](#); [Voyager 2](#)

Definition

The Voyager mission was designed to take advantage of a rare geometric arrangement of layout of ► [Jupiter](#), ► [Saturn](#), ► [Uranus](#), and ► [Neptune](#), which occurs about every 175 years. This allowed for a four-planet tour for a minimum of propellant and trip time. The flyby of each planet bends the spacecraft's flight path and increases its velocity

enough to deliver it to the next destination. Using this “gravity assist” technique, the flight time to Neptune was reduced from 30 to 12 years.

Both spacecraft were launched from Cape Canaveral: Voyager 2 was launched first, on August 20, 1977; and Voyager 1 was launched on a faster, shorter trajectory on September 5, 1977.

Overview

The prime mission to Jupiter and Saturn brought Voyager 1 to Jupiter on March 5, 1979, and Saturn on November 12, 1980, followed by Voyager 2 to Jupiter on July 9, 1979, and Saturn on August 25, 1981. Voyager 1’s trajectory, designed to send the spacecraft close to Titan and behind Saturn’s rings, bent the spacecraft’s path northward out of the ecliptic plane. While Voyager 2 was aimed to fly by Saturn at a point that would direct the spacecraft toward Uranus, Voyager 2 encountered Uranus on January 24, 1986, returning detailed photos and other data on the planet, its moons, magnetic field, and dark rings. Following Voyager 2’s closest approach to Neptune on August 25, 1989, the spacecraft flew

southward, below the ecliptic plane, and onto a course that will take it, too, to interstellar space. Voyager 1, meanwhile, continues to press outward, conducting studies of interplanetary space. Since September 2013, it is announced that Voyager 1 is in the interstellar space more than 19 billion kilometers (or 127 AU) from the Earth. NASA announced in December 2018 that Voyager 2 entered also the interstellar space.

The energy production by the radio-isotopic thermoelectric generator based on the nuclear decay of plutonium is regularly decreasing. The instruments are then progressively turned off to maintain sufficient power margins. The energy supply is supposed to last up to 2025.

The spacecraft reach, in 2022, more than 44 years of continuous operations. In April 2022, both spacecraft are sending data from their respective locations about the physical border between the solar system and the interstellar space. Voyager 1 travels at about 21 light hours (23,27 billion of km) from the Earth at almost 61,000 km/h and 4 instruments out of 10 are “On”: the Cosmic Ray telescope, the Low Energy Charged Particle experiment, the Magnetometer, and the Plasma Wave experiment. Voyager 2 travels at about 18 light hours (19,48 billion

km) at about 55,000 km/h from the Earth with the same four instruments “On” plus the Plasma Spectrometer.

According to the Jet Propulsion laboratory, Voyager 1 will pass the Oort cloud, getting out of the zone of attraction of the Sun, within 14,000 to 28,000 additional years. . .

As the Pioneer 10 and 11 spacecraft, while they are leaving the solar system, both Voyager spacecraft are loaded with a gold-plated record disk, initiated by Carl Sagan, that contains pictures and sounds from the Earth as well as greetings from human beings (Figs. 1 and 2).

explosion. It is currently in a state characterized by substantial mass loss from its surface, which creates a dense circumstellar envelope, with a complicated morphology, which is rich in primarily oxygen-bearing species and cosmic dust (most likely in the form of silicates). The oxygen-rich nature of its circumstellar matter (i.e., the abundance of oxygen is higher than that of carbon) limits somewhat the chemical complexity, but more than 20 circumstellar molecular species have been detected. Noteworthy is the presence of aluminum, phosphorus, and titanium oxides.

WASP Wide Angle Search for Planets

Definition

WASP: A ground-based survey covering most of the sky looking for exoplanet transits.

History

After trials with a single-camera “WASP0” prototype, the first WASP survey instrument was installed in 2003 at the Observatorio del Roque de los Muchachos on La Palma (Pollacco et al. 2006). It operated during 2004 as a manned facility, equipped with 5 cameras based on Canon 200-mm, f/1.8 lenses backed by 2x2k CCDs. Data acquired led to the first three WASP planet discoveries: WASP-1b, WASP-2b, and WASP-3b (Collier-Cameron et al. 2007; Pollacco et al. 2008). A companion facility, WASP-South, was then constructed at the Sutherland station of the South African Astronomical Observatory. From 2006 onwards, both WASP-South and the upgraded La Palma “SuperWASP” ran as robotic, eight-camera facilities. In 2012, WASP-South switched to 85-mm, f/1.2 lenses in order to survey brighter stars. The WASP facilities continued operating until 2014. Overall, the WASP project has led to the discovery of over 190 gas-giant exoplanets transiting stars brighter than visual magnitude $V \sim 13$.

Overview

The WASP survey (Wide Angle Search for Planets), which operated from 2004 to 2014, was one of a number of ground-based surveys aimed at surveying large regions of sky in order to detect the dips in stellar light-curves caused by transiting exoplanets. Similar projects, overlapping with WASP in both aims and timescale, included HATnet, the TrES survey, the XO project, the OGLE microlensing project, KELT-North and KELT-South, the Qatar survey, MASCARA, and the HATSouth project. Until the launch of the TESS spacecraft in 2018, the space-based transit surveys (first CoRoT, then Kepler, and Kepler’s

K2 extension) were limited to relatively small fields of view. Thus the ground-based projects were the first to survey much of the sky, and, while lacking the space-quality photometry needed to detect rocky planets, were capable of detecting the $\sim 1\%$ dips caused by transits of Jupiter-sized gas giants. In particular, the class of “hot Jupiters” were easy prey, partly because their short-period orbits mean that they transit often, and also because they are often bloated in size, owing to irradiation and tidal effects, and so produce deeper transit dips than a “cold” Jupiter. Indeed, the bloated radii of short-period gas giants meant that Saturn-mass and even Neptune-mass planets could be found. Since bloated, fluffy exoplanet atmospheres are the easiest to characterize with spectral analysis, many of the gas giants found by WASP and other ground-based surveys have become prime targets for the detailed study of exoplanets and their atmospheric compositions (e.g., Spake et al. 2018).

The WASP project operated two 8-camera arrays, SuperWASP on La Palma in the Northern hemisphere, and WASP-South in South Africa. They monitored sets of fields every clear night, observing each field every 10–15 mins. Between 2004 and 2014, they recorded seven million CCD frames, producing 580 billion photometric data points on over 30 million different stars. Automated searching followed by human assessment led to 2000 transiting-planet candidates. Only a tenth of these would prove to be real (the remainder being transit mimics, such as blended eclipsing-binary stars). Discovering the planets thus required a follow-up campaign involving hundreds of nights of telescope time. In the South, the CORALIE spectrograph on the 1.2-m Swiss/Euler telescope combined with photometry from the 0.6-m TRAPPIST telescope to pursue the WASP-South candidates (e.g., Hellier et al. 2012). In the North, the follow-up was mainly with the SOPHIE spectrograph at the Observatoire de Haute-Provence. In total, over 190 exoplanets have been discovered by WASP, most with host stars of visual magnitude between $V = 9$ and $V = 13$.

Notable WASP discoveries include: WASP-8b (Queloz et al. 2010; a hot Jupiter in a highly

eccentric orbit), WASP-12b (Hebb et al. 2009; with material boiling off its surface, and with an orbit showing tidal decay), WASP-17b (Anderson et al. 2010; discovered in a retrograde orbit, and bloated to 2 Jupiter radii), WASP-18b (Hellier et al. 2009; with the strongest planet-star tidal interaction of any known planet), WASP-19b (Hebb et al. 2010; the shortest-period hot Jupiter), WASP-30b (Anderson et al. 2011; the first transiting brown dwarf discovered), WASP-33b (Collier-Cameron et al. 2010; the first hot Jupiter found transiting an A-type star), WASP-43b (Hellier et al. 2011; the closest-orbiting hot Jupiter, and prime target for “phase curve” observations), WASP-47b (Hellier et al. 2012; which K2 found to have two rocky companion planets), WASP-76b (West et al. 2016; a prime target for atmospheric characterization, with “iron rain”), WASP-80b (Triaud et al. 2013; a hot Jupiter transiting an M-type star), WASP-107b (Anderson et al. 2011; a bloated, Neptune-mass planet where metastable helium was discovered), WASP-103b (Gillon et al. 2014; a planet on the edge of tidal disruption), WASP-121b (Delrez et al. 2016; an archetypical “ultra-hot Jupiter”), and WASP-166b (Hellier et al. 2019; a bloated, Neptune-mass planet transiting a bright star).

Definition

Water is a tasteless and odorless molecular compound formed from two atoms of hydrogen and one of oxygen (H_2O), being thus the oxide of hydrogen or the hydride of oxygen. As hydrogen and oxygen are themselves among the most abundant atoms in the Universe (#1 and #3, respectively), water is also an extremely abundant

molecule in the universe, being formed as a by-product in star-forming regions.

Overview

At standard atmospheric temperature and pressure (1 atm, 25 °C), pure water is a liquid. At the same pressure, water undergoes a phase transition to a solid (water ice) at 0 °C and a phase transition to a gas (water vapor) at 100 °C (see Fig. 1).

Liquid water, although it covers some 70% of the Earth's surface, and may occur in subsurface environments of other rocky planets such as Mars or some moons of the outer planets (e.g., Europa and Enceladus), and in the interiors of some asteroids and possibly transiently in comets where temperature and pressure conditions are sufficient to keep water in the appropriate region of its phase diagram, is rarely encountered in the universe (see ► [Water in the Universe](#)). Water occurs much more commonly in the gas phase in the interstellar medium, or as a solid in ices, either in icy planets or moons, comets and interstellar dust grains, or associated with hydrated mineral phases.

Water, Fig. 1 The pressure-temperature phase diagram of pure water. The various phases of water are indicated and Roman numerals used for some of the different possible phases of ice. Mean surface conditions on Mars, Earth,

and Titan are indicated. Under current atmospheric pressure, water ice on Mars' surface would sublime directly to the vapor

Due to the difference in electronegativity of the oxygen and hydrogen atoms, water molecules have a dipolar moment and are able to form intermolecular hydrogen bonds between molecules which contribute to its unusual properties, such as its high viscosity, boiling point, surface tension, heat of vaporization, specific heat capacity, and latent heat of fusion (see ► [Water, Solvent of Life](#)). These properties make water an especially good solvent for a wide range of molecules and contribute to its facilitation of chemical reactions and mineral weathering. Water's physical properties are also believed to contribute to the habitability of planets, as water is largely transparent in the visible region of the electromagnetic spectrum in which photosynthesis occurs, but considerably opaque in the UV and infrared regions, shielding organisms from radiation damage and contributing to the greenhouse effect that helps keep planetary surfaces warm, respectively.

[Available water](#); [Free water](#)

Definition

Water activity, a_w , is a dimensionless parameter defined as the vapor pressure of water in a system (p) divided by that of pure water at the same temperature (p_o). It correlates with the proportion of water available for biological or chemical reactions and is related to the energy status of the water molecules in a given system (pure distilled water has $a_w = 1$).

Overview

a_w measures how efficiently the water present in a system, including, for example, microbial cells, can take part in a reaction or in a physical process and is often also referred to as the “free” or “available water” in a system.

For an ideal solution,

$$a_w = \frac{n_1}{n_1 + n_2} = \frac{p}{p_0}$$

where n_1 refers to moles of water, n_2 refers to moles of solute, and p , p_0 refer to the vapor pressure of solution or solvent, respectively.

a_w is temperature dependent since it is associated with the amount of free, unbound water in the system and changes on the temperature of the system, which strongly affects parameters like

Water Activity, Fig. 1 Water activity limits for the growth of different microorganisms

water binding, water dissociation, and solubility of dissolved compounds. Water activity is related, in a nonlinear way, to moisture content at a given temperature, which is represented as a sorption isotherm.

a_w affects growth, sporulation, toxin production, and survival during storage of microorganisms. The bars in the figure indicate the limits of growth of microorganisms commonly present in foods. Common bacteria do not grow at water activities below 0.9, and no microbial growth occurs below 0.6. In some cases, when a_w limit for growth is reached, sporulation occurs. Therefore, water activity is an important parameter related to the control of bacterial growth and determines the shelf life of many foods. a_w values of foods are precisely measured with the help of capacitance hygrometers or dew-point hygrometers, both of which are commercially available.

At high a_w values, food substances tend to support more microorganisms; therefore, lowering the water activity by drying or salting foods is an important way to preserve food since plasmolysis occurs when cells are subjected to lower a_w as a result of an increase in osmotic pressure. In addition, low a_w can help to reduce the rates of adverse reactions to food preservation such as

browning, protein denaturation, fat oxidation, or vitamin degradation. Common solutes that decrease a_w are NaCl, KCl, glucose, sorbitol, fructose, and sucrose. In contrast, bacteria and mold can synthesize soluble compounds like amino acids, sugars, glycerol, or charged ions like K^+ that accumulate in the cytoplasm and contribute to an increase in a_w . However, the minimum a_w for growth is affected by other factors such as pH, temperature, nutrient availability, and presence of antimicrobial substances (Fig. 1).

Definition

Water is ubiquitous in the Universe and also present in all kinds of solar-system objects. This molecule, made of two ► [hydrogen](#) atoms and one oxygen atom, has played a key role in the formation of solar-system bodies and in the evolution of the ► [terrestrial planets](#).

Overview

Water is one of the most abundant molecules of the Universe, which is a consequence of the high cosmic abundance of its two components, hydrogen and oxygen (see ► [Water in the Universe](#)). It is a major component in the solar system, especially in its outer parts where it is mostly in the form of ice. The ► [Earth](#) is presently the only place where water is present in substantial quantities in all of its three states: solid, liquid, and vapor. Water vapor and ice can be found on ► [Mars](#); on the Moon and Mercury, water ice may be present in permanently shaded craters near the poles. Water can also be present as a minor constituent in rock both on the surface and the interior. In a planetary interior, water may have

a major effect on the rheology and the heat transfer mechanism and rate. For the upper Earth mantle, the concentration may differ from that in the Earth's lower mantle. The concentration of water in the interior of the terrestrial planets is not well known but has been speculated to possibly reach values similar to the Earth mantle at least for Mars.

Apart from its high abundance, water has specific chemical properties that explain its key role in astrochemistry. Due to its large dipole moment, liquid water is a very good solvent, which makes possible the development of complex chemical reactions. In addition, water is liquid over a large temperature range, as compared to other molecules. In a ► [protoplanetary disk](#), as in the protosolar disk, water is the first simple molecule to condense as the temperature decreases (beyond the ► [snow line](#)). Another interesting property is the density of water ice which is lower than that of liquid water; as a consequence, a liquid ocean can be protected by an icy upper layer if the temperature drops below the water freezing point at the surface.

Water has several isotopes (HDO, D₂O, H₂¹⁷O, H₂¹⁸O). The most interesting one is HDO ("heavy water"), observations of which are used in the outer solar system to probe the temperature of the medium where the molecule has been formed. Indeed, as observed in the ► [interstellar medium](#) and as studied in the laboratory, at low temperatures, HDO is enriched versus H₂O with respect to their protosolar abundances, as a result of ion-molecule or molecule-molecule reactions. In the case of terrestrial planets, the ► [D/H \(deuterium/hydrogen\) ratio](#) is also a diagnostic of an early atmospheric escape.

Another interesting property of water is linked to its two states, ortho and para, associated to the spin directions of its two hydrogen atoms. The two states have slightly different spectroscopic transitions, which can be used to determine the ortho/para ratio (OPR) of the molecule. This provides another diagnostic of the formation temperature of the molecule; such measurements have been made in the case of comets.

The Formation Scenario of the Solar System

It is generally accepted that the solar system was formed after the collapse of an interstellar rotating cloud that gravitationally fell into a disk. The proto-Sun was formed at the center from the accretion of the surrounding matter. In the turbulent disk, particles accreted through mutual collisions; some ► [planetesimals](#) grew and formed planets, attracting by gravity the neighboring particles.

Within the protosolar disk, the amount of solid matter available to form planetesimals depends upon the temperature. Near the Sun, at temperatures of a few hundred kelvin, only heavy elements (silicates, metals) are in solid form. Because these elements are formed by stellar nucleosynthesis, their abundance is very small, as shown by the table of cosmic abundances. Planets formed at these heliocentric distances are dense and relatively small: they are the terrestrial planets, also called rocky planets. In contrast, at larger heliocentric distances, where the temperature drops below about 200 K, more abundant molecules start to form ices. The first (and also the most abundant) one is water. Other simple molecules (NH_3 , H_2S , CO_2 , CH_4 , etc.) condense at larger heliocentric distances. Rock-ice cores are formed, with a mass that can reach 10–15 terrestrial masses. Above this threshold, the gravity field of these cores is sufficient to capture the surrounding gas, mostly made of hydrogen and helium. This process leads to the formation of ► [giant planets](#), with a huge mass and volume but a low density. It also explains the presence of the regular satellites, found in the equatorial plane of the giant planets.

In the planetary formation process, water plays a key role, as the distance where the molecule condenses marks the limit, at about 180 K, between the terrestrial and giant planets. This limit, called the snow line, was at about 3–4 AU from the Sun at the time of the planet's formation. Presently, after the cooling of the protosolar disk, the limit is closer to about 2 AU, as observed from the water outgassing of comets.

Water in Comets

The volatile content of comets can amount to about 80% of water by mass. The study of water is very informative for cometary research. The analysis of the water rotational or rotational-

vibrational transitions at high spectral resolution allows the study of the kinematics and the physical properties of the inner coma. In addition, as mentioned above, the measurement of D/H and the ortho/para in comets brings information about their formation temperature. The ortho/para ratio, measured in a few comets originating from the ► [Oort cloud](#), indicates a low formation temperature, typically around 30 K or below. The D/H ratio, also measured so far on a few Oort cloud comets, is 3×10^{-4} , that is, 15 times the protosolar value and 2 times the terrestrial value. The large enrichment, as compared to the protosolar value, is a consequence of the ► [deuterium](#) enrichment in the ice at low temperatures. The enrichment with respect to the terrestrial value is an important diagnostic, as it shows that Oort cloud comets cannot be the only reservoir for the terrestrial water. The D/H ratio in the terrestrial oceans is actually close to the D/H ratio measured in the outer edge of the main asteroid belt, which could be the main reservoir for the water on Earth. An alternate hypothesis was brought in 2012 with the measurement of D/H in a Kuiper belt comet, 103P/Hartley 2, by the Heterodyne Instrument for the Far Infrared (HIFI) heterodyne spectrometer of the Herschel Space Observatory. The inferred D/H ratio was found equal to the terrestrial value, which suggests that Kuiper Belt comets might be, at least partly, at the origin of the ocean water.

Water in the Giant Planets

Water is present both in the interior and the upper stratospheres of the ► [giant planets](#). Water vapor has been detected in the lower ► [tropospheres](#) of ► [Jupiter](#) and ► [Saturn](#) by infrared spectroscopy around 5 μm (a spectral window where the radiation comes from deep levels) and, in addition, by the Galileo probe in the case of Jupiter. In the case of ► [Uranus](#) and ► [Neptune](#), tropospheric water vapor cannot be detected because H_2O is in the form of ice at observable levels (a few bars).

A surprising discovery was the detection of water vapor in the upper ► [stratospheres](#) of giant planets and ► [Titan](#) by the ISO satellite, in 1997. The water emission lines were later analyzed in more detail by the Herschel Space Observatory, in operation between 2009 and 2013. The thermal vertical profiles of the giant planets all exhibit a

tropopause where the temperature, ranging between 50 and 110 K, is always below the water freezing temperature. As a result, the water observed in their stratospheres cannot come from their interior, as the tropopause acts as a cold trap. Thus, the stratospheric water of the giant planets and Titan must be of external origin. This origin could be local (rings, satellites) or interplanetary (comets, micrometeorites). Following the Herschel observations, it appears that the origin of stratospheric water in Jupiter is probably the result of the collision of comet Shoemaker-Levy 9 with the planet in 1994. In the case of Saturn, the detection and analysis of the water torus of Enceladus by Herschel indicates that this torus is the most plausible source for stratospheric water on Saturn but not on Titan.

Water in the Rings and Outer Satellites

All ring systems of the giant planets are mostly made of water ice, with the exception of the tenuous ring of Jupiter, fed by inner satellites. In the case of Uranus and Neptune, the rings are dark, probably as a result of a hydrocarbon deposit due to their irradiation by high-energy particles (see ► [Planetary Rings](#)).

The Galilean satellites Ganymede and Callisto have major shares of water, about one-third by mass for both. ► [Europa](#) has a relatively thin water layer of 150 km thickness, equivalent to about 8 wt.%. No water ice has been found on ► [Io](#), Jupiter's closest satellite, which is subject to strong tidal forces and exhibits active volcanism. Europa, the next satellite in distance from Jupiter, is of particular interest for astrobiology, as it is almost certain to have an internal ocean of saltwater in contact with a rocky crust at its bottom. Ganymede and Callisto also are likely to have internal oceans, but these are sandwiched between ice layers thus probably limiting the supply of nutrients. In addition, the ice shell above the ocean is likely to be around 100 km or thicker, while for Europa the ice shell is only a few tens of kilometers thick on average. Some models even have an ice shell only a few kilometers thick for Europa. Water ice is the main constituent of most outer satellites as indicated by their average densities close to $1,000 \text{ kg m}^{-3}$. In the case of ► [Titan](#), water ice is also present in its interior

and at its surface, as the boulders shown by the images of the ► [Huygens](#) probe are most likely made of water. Another interesting outer satellite is ► [Enceladus](#), which probably feeds the E-ring of *Saturn*, where active ► [cryovolcanism](#) (mostly driven by water) has been discovered by the ► [Cassini](#) orbiter. As mentioned above, the water torus of Enceladus was detected for the first time by the Herschel Space Observatory.

The Role of Water in the Evolution of Terrestrial Planets

The atmospheres of ► [Venus](#), the Earth, and Mars show remarkable differences in their physical conditions, with surface temperatures and pressures ranging from 730 K and 90 bars (Venus) to about 230 K and 0.06 bar (Mars). In between, the Earth, with a surface temperature of 288 K and a pressure of 1 bar, has the capability of keeping water in the form of liquid oceans. Still, the primitive atmospheres of the three planets probably had a similar composition, with a large fraction of CO_2 , a small percentage of N_2 , and, possibly, substantial amounts of water. It has been suggested that Venus and Mars had a large initial water content based on two pieces of evidence. First, the D/H ratio of these planets is, with respect to the terrestrial value, substantially enriched in the case of Venus (by a factor at least 120) and still significantly enriched in the case of Mars (a factor 5). This has been interpreted as the signature of massive early water outgassing, especially in the case of Venus, although other interpretations are possible. The second diagnostic is, in the case of Mars, the evidence from the surface relief and mineralogy (detection of phyllosilicates and sulfates) that liquid water has been present at the Martian surface in its early history.

Why did the terrestrial planets evolve toward so different states? Water may have played a major role in these divergences. Indeed, the surface temperature of these planets now is such that water has to be in the form of vapor on Venus and solid + vapor on Mars (although it could be liquid for some time before it evaporates) but is mostly liquid on the Earth. In the past history of Venus, water may have been liquid at its surface, due to the fainter radiation of the young Sun. As the solar radiation increased to reach its present level, water

would have evaporated. The atmosphere, with both water vapor and ► [carbon dioxide](#), would have experienced a huge ► [greenhouse effect](#) which led to the present conditions.

In the case of Mars, another factor must be considered: the mass of Mars is about one-tenth of the terrestrial mass. Due to the lower internal energy and a smaller gravity field of the planet, the primitive atmosphere of Mars must have been more tenuous than those of Venus and the Earth. Still, it must have been thicker than today and also warmer to allow the presence of liquid water and account for the enriched D/H ratio. The Martian atmosphere may have escaped when the internal activity ceased to supply water vapor to the atmosphere and the internal dynamo ceased to supply a global magnetic field. The atmosphere might also have lost the water as a consequence of a major impact.

In the case of the Earth, atmospheric water condensed very early to form the oceans, as shown by the presence of zircons in Archaean rocks in Western Australia. The atmospheric carbon dioxide was trapped in the oceans in the form of calcium carbonate, which led to a moderate greenhouse effect and allowed the temperature to stay more or less constant over the planet's history. The Earth probably experienced phases of almost complete glaciations, especially at the beginning of its history when the solar radiation was fainter; however, the planet's internal energy must have been sufficient to warm the atmosphere through volcanism.

Conclusions and Open Questions

There are many open questions regarding water in the solar system. In the case of comets, what is the D/H ratio for ► [Kuiper belt](#) comets? In the case of the giant planets, what is the O/H value below the clouds? In the case of Jupiter, the Galileo probe entered a dry region of subsidence and its O/H measurement was not representative of the whole planet. In the case of Mars, the search of water is an ongoing challenge for future space missions.

The special role of water in the formation and evolution of the solar system must be the consequence of its unique physical and chemical properties; we can thus expect water to play a similar key role in extrasolar planetary systems.

Overview

► **Water** is one of the most abundant molecules in the Universe. This is not surprising, as water is made up by two of the most abundant elements in the universe, hydrogen and oxygen. Water is widespread in the molecular phase of the ► **interstellar medium** (see also ► **Molecular Clouds**). It is found in both the coldest and warmest regions of space. A very important fraction ($>1/3$) of all elemental oxygen not trapped into the refractory component of the interstellar grains is locked into water molecules, either as ice mantles on the interstellar grains or in the gas phase.

► **Water** in the solar system is covered in a separate entry.

Water as Ice and Gas

In the interstellar medium, water molecules are found in the following states:

1. In cold (≤ 100 K) molecular clouds, oxygen and hydrogen atoms stick onto the dust grain surfaces and form water ices around the refractory component of the grains (composed by silicates and carbonaceous material; see ► **Interstellar Ices**). These ices are also called grain mantles. It is estimated that about one-third or more of the elemental oxygen is locked into the grain mantles.
2. In warm (≥ 100 K) regions, usually associated with star-forming regions (see also ► **Star Formation: The Observations**), ices are sublimated and the water molecules are released into the gas. Important regions where this phenomenon occurs are the ► **hot cores** and ► **hot corinos**, regions surrounding new forming stars.
3. Water molecules can also be sputtered from the grain mantles in mild to violent (<100 km/s) shocks (see also ► **Shock, Interstellar**). The amount of water molecules released into the gas phase depends on the shock velocity, and it can reach a substantial fraction (10% or more) of that contained in the grain mantles. If extremely violent, the shock can destroy completely the grains, and molecules from the whole mantle would be, in this case, released into the gas phase.
4. Another mechanism thought to release the frozen water molecules from the grain mantles to the gas phase is the ► **photodesorption** of the ices. Ultraviolet (UV) photons, usually those emitted by young stars, hit the grains and lift off water molecules at the surface of the ice coating. The mechanism can be relatively efficient in the presence of strong UV fields.
5. In very warm (≥ 220 K) regions, reactions forming water in the gas phase become very efficient and water molecules can contain all the oxygen in the gas phase not locked into the CO molecules. Typical regions where this phenomenon occurs are (some) hot cores, hot corinos, and shocks.

How water is formed in the various situations, following which formation and destruction pathways, is still a matter of debate and will not be further described here. Both the excitation and the chemistry of water in various astronomical

environments are discussed by van Dishoeck et al. (2014).

Deuterated Water, HDO

The chemistry associated with the formation of the water isotopologue HDO, where a deuterium atom substitutes one of the two hydrogen atoms, is particularly relevant in the astrobiology context for two reasons:

1. HDO lines are more easily observable than H_2O astronomically (see ► [Basic Methodology](#) below) and can, therefore, be used to probe the presence of water in different circumstances.
2. The HDO/ H_2O abundance ratio is a valuable probe of the conditions prevailing when water is formed: for example, observations of the HDO/ H_2O abundance ratio in ► [comets](#) and terrestrial oceans provide important clues on the solar system's history (see also Ceccarelli et al. 2014 and ► [Oceans, Origin of](#)).

In the Universe, there is one deuterium atom for about every 31,000 hydrogen atoms (see ► [Deuterium](#)). Therefore, HDO should be 62,000 times less abundant than H_2O . However, in a cold medium, the HDO/ H_2O ratio can be enhanced by several orders of magnitude and reach the level of a few percent. This is caused by a peculiar chemistry that takes place in cold ($\leq 20\text{--}30\text{ K}$) environments and is basically due to the difference in the quantum mechanical ground-state energy of a deuterated species relative to its nondeuterated equivalent (see ► [Isotopic Fractionation \(Interstellar Medium\)](#) and Ceccarelli et al. 2014). In practice, large ($>10^{-3}$) HDO/ H_2O ratios can only be produced in cold ($< \text{about } 20\text{--}30\text{ K}$) gas or in warm ($>200\text{ K}$) gas illuminated by a strong UV field. In addition, exchange of deuterium (in the two directions, from and to) with other deuterated species may also occur in the water ice on interstellar grain surfaces.

Observations provide upper limits to the degree of water deuteration in interstellar water ice: HDO is less than about 1% relative to H_2O . On the contrary, HDO has been observed

as high as a few percent in the gaseous phase, specifically in hot cores, hot corinos and protostellar molecular shocks (see also ► [Chemistry](#)). In most comets, the HDO/ H_2O ratio has been measured to be around $1\text{--}5 \times 10^{-4}$, i.e., more than ten times larger than the elemental deuterium/hydrogen ratio.

Water During the Formation of a Solar-Type Star and Associated Planetary System

It is worth summarizing the cycle of water during the star formation process and, in particular, during the formation of a solar-type star and its planetary system (see also [Star Formation](#); ► [Protoplanetary Disk](#), [Chemistry](#); and van Dishoeck et al. 2014 and Caselli and Ceccarelli 2012). The following points give a brief summary, beginning with the dense core in a molecular cloud that will form the star:

1. During the pre-collapse phase, water molecules are largely frozen onto the grain mantles and only a very small fraction remains in the gas-phase, with an abundance of $\text{H}_2\text{O}/\text{H}_2 < 10^{-9}$. Since the medium is very cold ($<10\text{ K}$), it is believed that the HDO/ H_2O ratio in the water ice is enhanced, but no observations can prove (or disprove) that, so far.
2. Once the collapse starts, matter falls from the envelope toward the central newborn star, releasing the gravitational energy as radiation. Matter in the innermost envelope heats up, and the grain mantles formed during the pre-collapse phase sublime. In the hottest regions, where the gas temperature exceeds about 250 K , water is also formed by gas-phase reactions (see above). Large abundances ($\text{H}_2\text{O}/\text{H}_2 > 10^{-5}$) have been measured, although the exact values need confirmation.
3. Simultaneously with the collapse, a relevant fraction of matter is ejected out from the center at large velocities ($>100\text{ km/s}$). When the outflowing gas hits the surrounding medium, various shocks are created, the gas is compressed and heated, and water is again either sputtered from the grain mantles or formed in the gas phase. The shocked gas cools down once the shock passes and again forms ices.

- In this case, the HDO/H₂O ratio of the ices is relatively small, as warm water condenses fast on the ices.
4. As time passes, the envelope surrounding the newborn star is dispersed and only the surrounding protoplanetary disk remains. The innermost regions are warm and water ice sublimates. However, a large fraction of the disk is cold and water is frozen onto the grain mantles. Here the intense UV field emitted by the newborn star plays a key role in releasing water into the gas phase (via photodesorption; see above) and also in enhancing the HDO/H₂O in the innermost, warm gas. Water vapor has been measured with large abundances, H₂O/H₂ ≤ 10⁻⁴, in the innermost regions of the disk, whereas only upper limits exist of the abundance in the outermost, cold disk, H₂O/H₂ < 10⁻⁶.
 5. Dust grains in the protoplanetary disks coagulate into the planetesimals that eventually will form larger bodies: the bulk of rocky planets, asteroids, and comets. In the disk midplane, the temperature is low and water is frozen again onto the grains. As in the pre-collapse phase, the HDO/H₂O ratio is thought to be greatly enhanced in the ice of the outermost disk. Finally, ices in the comet formation region of the disk may also have enhanced HDO/H₂O ratios caused by reactions between neutrals involving OH and OD. So far, no observations exist of the HDO/H₂O in disks.

Water in the Distant Universe

Water has been detected in several external galaxies, notably by observation of the water maser line at 22 GHz and, in fewer cases, by observations of water thermal (non-masing) lines. The most distant galaxy where water has been detected so far lies at a redshift of 4.7.

Basic Methodology

With the exception of in situ experiments, namely, probes sent to the Moon or Mars or comets, water in the universe is detected and measured indirectly by the photons that it absorbs or emits, as for any

other molecule in space. What photons, namely, at what wavelengths, are emitted or absorbed depends on the water status, whether in the gas phase or as solid ices. Water ice has specific bands in the near infrared (see also ► [Infrared Spectroscopy](#)), which are typically a fraction of a micron wide. On the contrary, gaseous water has lines in the millimeter to infrared wavelength range that are much narrower, typically a few megahertz wide. Since water is present in the Earth's atmosphere, the detection of water in the universe usually requires observations from space telescopes. So far, there have been a few telescopes that have provided observations of water in space: the ► [Infrared Space Observatory](#) (ISO), the Submillimeter Wave Astronomy Satellite (SWAS), the Odin telescope, the ► [Spitzer Space Telescope](#), and the Herschel Space Observatory. In addition, a few water ► [maser](#) lines can be observed with ground-based telescopes, notably the 22 GHz line in the radio spectral region. In this context, the isotopologue of water, HDO, which has several lines accessible with millimeter and submillimeter ground-based telescopes, provides a very precious pathway to probe the presence of water. Similarly, the even rarer isotope D₂O has transitions observable with ground-based telescopes.

In general, water ice is observed in absorption, whereas gaseous water can be in absorption or emission, depending on the temperature and density of the gas and dust. Water ice (whose bands are at about 3, 6, and 13 μm) can only be observed when a bright infrared source lies behind the gas cloud. The same applies also in the case of water in cold gas: the photons emitted by the bright source behind (usually emitted by the dust) are absorbed by the water molecules between the infrared or submillimeter source and the telescope, with the result that the spectrum shows a dip at the wavelengths of the water bands or lines.

The intensity of the water lines in emission, but also in absorption, depends on the gas (and dust) temperature and density, in addition to the abundance of the water. In practice, estimating the abundance of gaseous water from observations is a relatively complex problem, which critically depends on our knowledge of the microphysics

of the water molecule and its mixing with dust. It involves computing exactly how the energy is passed by collisions from the H₂ molecules to the internal energy of the H₂O molecule and vice versa as well as the radiative pumping from dust photons. The former is a complex problem of quantum mechanics that only recently has been correctly solved and addressed.

Future Directions

Since space telescopes are required to observe water lines, a lot still remains to be understood about water in the Universe: its chemistry and role during the star formation process and, in general, in the ► [interstellar medium](#), both galactic and extragalactic. In the near future, the James Webb Space Telescope, launched in the winter 2021, will provide new data on the water ices as well as the water vapor abundance and status in the warmest regions of weak, very young protostars and protoplanetary disks. We will know much more about the cycle of water, in particular during the star formation process, including how water is formed and destroyed during each phase. Ultimately, this will help us to understand the heritage received by the Earth from the very first phases of formation of our solar system.

Definition

The origin of the Earth's water is one of the most important questions in determining the prerequisites for a habitable planet. Calculations of the temperature of protoplanetary material at the Earth's orbital radius have suggested that the Earth's original water content may have been very low. The primitive Earth may therefore have needed a mechanism to deliver water-rich material from the outer Solar System. Current theory suggests that contributions from inward-scattered water-rich asteroids during formation could provide the necessary water, but other models for water delivery cannot be currently ruled out.

Overview

Hydrogen and oxygen forming water molecules on the present-day Earth could have been delivered in several different forms during the planetary accretion. Because there is no direct evidence of water delivery to the Earth, the origin of water can only be addressed by indirect approaches. Astrophysical models and observations of extrasolar protoplanetary disks provide information on possible processes occurring during planetary accretion. The actual processes that were significant to the evolution of the Earth need to be identified based on the chemical and isotopic records obtained from meteorites, cometary comae, interplanetary dust particles (IDPs), planetary atmospheres and the Sun, as well as the Earth itself.

In a star-forming gas disk, condensation of the nebula gas separates gaseous volatile elements from refractory elements depending on the heliocentric distance (thus on the temperature of the region). A condensation front for water ice called “snow line” was located around 2.7 AU in the early solar system. The condensates were “rocky” (dry) near the Earth's orbit because water remained in the vapor phase, whereas “icy” (water-rich) objects such as ► [comets](#) develop outside the snow line. Volatile-rich rocky materials, such as phyllosilicate minerals (i.e., hydrated clay minerals), occupy the intermediate region. The dust grains coagulated and accreted to form planetesimals, asteroids, and eventually planets while the nebula gas dissipated. As the protoplanet grew in size, the impact velocity of accretion increased. This caused volatilization of the colliding objects. The volatiles released at the surface of the accreting planet were lost to the space until the gravitational energy of the planet exceeded the kinetic energy of gas constituents. If the latter condition was fulfilled before the dissipation of the Solar nebula, the planet also captured hydrogen-dominated nebula gases. Hydrostatic stability of the proto-atmosphere could be disturbed by events such as large impacts and intense UV radiation from the T-Tauri phase of the young Sun, which resulted in erosion of the early water- or hydrogen-bearing atmosphere.

Numerous physical parameters remain unconstrained in this context, such as the feeding zone of the Earth, the rate of protoplanet growth, and the relative timing of the events. Being volatile, the behaviors of water and hydrogen are sensitive to physical and chemical conditions that are controlled by these factors. Moreover, the presence of water can significantly affect the fate of the planet. Deciphering the delivery and origin of water on Earth therefore involves detailed understanding of planetary evolution, which is essentially an identical problem to the origin of terrestrial atmosphere. Further discussion on the origin of water on Earth can be found in Morbidelli et al. (2000), Dauphas et al. (2000), Abe et al. (2000), Drake (2005), Marty and Yokochi (2006), and Mottl et al. (2007).

Basic Methodology

There are three categories of approaches for studying the origin of water on Earth: (1) numerical simulation that tracks the fate of condensed solid in the early solar system (Morbidelli et al. 2000; Ciesla and Lauretta 2005; Gomes et al. 2005), (2) modeling of the proto-atmosphere aimed to reveal the fate of volatile elements on accreting planets (Zahnle et al. 1990; Abe et al. 2000; Ikoma and Genda 2006), and (3) comparative isotopic and elemental studies of terrestrial and extraterrestrial materials, as well as mass balance constraints based on them (Pepin 1991; Dauphas et al. 2000).

Key Research Findings

Source of Water and Heliocentric Migration of Objects

In the absence of water in a solid phase within the region of the Earth's orbit, it is necessary either to capture water in gas phase or to bring in a water-bearing phase from the outer Solar System. Dynamical simulations of planetary accretion in the Solar System demonstrated that a few large, hydrous planetary embryos that grew in asteroidal belt could have migrated inward and delivered water to Earth, whereas the mean collision

probabilities of cometesimals with the Earth are too small to account for the delivery of water presently existing on our planet (Morbidelli et al. 2000). Due to gas drag, smaller (1 m size being the most efficient) phyllosilicate-bearing bodies could also be drifted inward during the early stage of accretion (Ciesla and Lauretta 2005). Both processes result in the delivery of carbonaceous chondrite-like materials to the Earth; thus, it would be difficult to distinguish these processes by chemical or isotopic records.

Finally, there are two possible ways of incorporating local (i.e., near the Earth's orbit) water in the Earth so that the heliocentric migration is not required. Stimpfl et al. (2006) showed that between one and three Earth ocean masses of water vapor from ambient solar nebula could be adsorbed into forsterite at temperatures of 500–700 K, which would subsequently be incorporated into planetesimals (Stimpfl et al. 2006; Drake 2005). The other possibility is a gravitational capture of hydrogen-dominated solar nebula gas as discussed below (Hayashi et al. 1979; Ikoma and Genda 2006).

Behavior of Water on the Earth During Planetary Accretion

As the size of the accreting body increases, both the impact velocity and the impact pressure of the projectile increase. Results of shock-loading experiments indicate that impact degassing of water from porous hydrous minerals starts at around 20 GPa, corresponding to the proto-Earth radius of 1500 km or 1.3% of its present mass (e.g., Lange and Ahrens 1982; Tyburczy et al. 2001). In order to retain the degassed water, the gravitational energy of the planet needs to exceed the kinetic energy of the water vapor. The kinetic energy of gas depends on the temperature, whereas the surface temperature of the accreting planet is controlled by the gravitational energy from accretion and radiative heat balance. These peculiarities are functions of the accretion rate, opacity, and blanketing effect of the atmosphere (Abe et al. 2000), which remains one of most enigmatic part of Earth's history. The same condition applies to the occurrence of gravitational capture of solar nebula. Ikoma and Genda (2006) set constraints on the mass of a planet with water

of nebular origin to be >0.3 of the Earth's mass based on a detailed model of the proto-atmosphere.

Giant impact and intense UV radiation from the Sun during its T-Tauri stage are currently recognized processes that could have disturbed the hydrostatic stability of the atmosphere, causing a substantial loss of the proto-atmosphere to the space (Kasting et al. 1984). Hydrodynamic escape can result in isotopic and elemental fractionations of gas species, and clear evidence of such event is recorded in the isotopic composition of ► [noble gases](#) in the atmosphere (► [Earth's Atmosphere, Origin and Evolution of](#)). The implications of this event to water delivery on Earth are as follows: (1) the current abundance of hydrogen (or water) represents only a small fraction of what had been once brought to the Earth, and (2) the D/H ratio of terrestrial hydrogen could have been significantly modified. A model investigation of D/H fractionation during hydrodynamic escape suggested that this ratio could be fractionated by up to a factor of 9 (Genda and Ikoma 2008). This result warns that direct comparison of this ratio to potential precursors could be misleading.

Elemental and Isotopic Constraints

The D/H ratios of potential precursors vary significantly, from the Solar nebula value (25×10^{-6}) to that of three comets from the Oort cloud (370×10^{-6}), whereas ► [carbonaceous chondrites](#) have intermediate bulk D/H ratios within $130\text{--}180 \times 10^{-6}$ (see Marty and Yokochi 2006 for review). This value is comparable to that of the Earth's ocean at 153×10^{-6} . This similarity is frequently used as a major argument for chondritic and against solar or cometary origin of water on the Earth. Given the possibilities of isotopic fractionation mentioned above, it merits further investigation.

The scenario of water delivery to Earth needs to be consistent with the observed abundances of other volatile elements on Earth. Noble gases in the atmosphere have two important characteristics that help understand the processes which affected volatile elements at the surface of the Earth: (1) the general enrichment in heavier isotopes and elements of noble gases compared to the Sun and (2) the “missing Xe” problem. Mars and

the Earth have a deficiency in Xe relative to other noble gases when compared to the meteoritic composition. Laboratory experiments simulating the formation of comets revealed that high concentrations of noble gases are trapped in amorphous water ice and exhibit a clear depletion in Xe relative to Kr (Bar-Nun and Owen 1998). Based on the low Xe/Kr ratio expected in comets, it has been suggested that the “missing Xe” problem of the terrestrial atmosphere could be a result of cometary contribution to the Earth (Owen et al. 1992). Note that the contribution of water from a comet could still be minor while significantly affecting the noble gas budget due to the high noble gas concentration in comets. Detailed modeling of mass balance and isotopic fractionation during hydrodynamic escape demonstrated that the cometary contribution could bring an exact outcome of noble gas elemental and isotopic composition of the terrestrial atmosphere (Dauphas 2003).

Future Directions

Several different approaches will further constrain the delivery processes of water to the Earth. Our knowledge of the D/H ratios and noble gas isotopic and elemental compositions in comets is limited at present, but is essential in order to estimate the cometary contribution to the terrestrial water budget. Investigating the volatile distribution of growing planets in extrasolar systems will help link the volatile budgets of potential precursors and the Earth and will provide useful constraints on dynamic modeling. Elemental and isotopic fractionation during the accretion and evolution of planets is a factor that should not be dismissed but has been little explored. A terrestrial inventory hydrogen including that present in the Earth's core is also indispensable for mass balance constraints.

[H₂O](#)

Definition

Water vapor can be formed in gas phase and on the ice mantles of dust grains (see “► [Water in the Universe](#)”). Once formed, the molecule is mainly destroyed by photodissociation through the effect of UV photons. In gas phase the molecule can be formed in low-temperature ► [clouds](#) through the chain of reactions:

In this set of reactions, H_2 is formed on the surface of dust grains, and H_3^+ is the product of the reaction of H_2^+ and H_2 . All the intermediate species producing H_2O in gas phase, OH^+ , H_2O^+ , and H_3O^+ , together with H_2O itself, have been observed toward a large number of astronomical objects using the Herschel satellite (van Dishoeck et al. 2013, 2014). Water can be destroyed in the gas phase through reactions with HCO^+ and H_3^+ producing H_3O^+ , CO , and H_2 .

At low temperature, water can be also formed on the surface of dust grains (see “► [Water in the Universe](#)” and van Dishoeck 2013, 2014).

At higher temperatures, water vapor can be also formed from the reaction of OH and H_2 , and OH itself is formed from the reaction of O and H_2 .

The photodissociation of water in space is produced mainly from the absorption of photons with wavelengths between 175 and 200 nm from the ground state to the first excited electronic state producing OH and H . Photodissociation with more energetic photons (Lyman alpha or X-rays) could also produce H_2 and O (see van Dishoeck et al. 2013).

The Herschel satellite has provided an incredible amount of observations of water in interstellar and circumstellar clouds, and in external galaxies (see van Dishoeck et al. 2021).

Water, Related Interstellar Radicals and Ions

William M. Irvine

Department of Astronomy, University of Massachusetts, Amherst, MA, USA

Synonyms

H_2O^+ ; H_3O^+ ; HO_2 ; HOOH ; OH ; OH^+

Definition

Several radicals, ions, and neutral molecules whose chemistry is related to that of water have been found in the interstellar medium. These include water itself, hydrogen peroxide (HOOH), H_2O^+ , HO_2 , OH , OH^+ , and H_3O^+ . For many of these species, the pure rotational transitions are in the terahertz frequency range, so that their detections have followed the recent availability of high-altitude or space-based telescopes such as APEX and Herschel. Details of such recent observations may be found in the links from the table of interstellar and circumstellar

molecules in the entry ► [Molecules in Space](#). In contrast, the ► [hydroxyl radical](#) (OH) was the very first molecular species detected by radio astronomers, observing at wavelengths around 18 cm the lambda-doublet transitions which arise from interaction between the molecular rotation and the motion of the unpaired electron. These lines have traditionally been used to estimate the water abundance in comets, since cometary OH is mainly produced by photodissociation of H₂O. ► [Maser](#) emission is observed astronomically from OH in the Milky Way and in external galaxies, as well as from H₂O.

The surprisingly high abundance of molecular oxygen, O₂, found in comet 67P/Churyumov-Gerasimenko by the Rosetta mission has been linked to the formation of hydrogen peroxide (H₂O₂) in the cometary water ice followed by sublimation of the ice and self-reaction of H₂O₂ to form H₂O and O₂ (Dulieu et al. [2017](#)).

H₂O; [Hydrogen oxide](#)

Definition

Liquid water is a colorless liquid whose molecules associate extensively through hydrogen bonding.

Overview

The water molecule, chemical formula H₂O, is composed of two hydrogen atoms (H) covalently bonded to a single oxygen atom (O). Two of the six outer-shell electrons of the oxygen atom are involved in covalent bonds with the hydrogen atoms and the remaining electrons are organized into two nonbonding (or lone) pairs. The four electron pairs surrounding the oxygen adopt an approximately tetrahedral configuration with an H-O-H angle of 104.5°. The positive and negative charges on the molecule are not distributed uniformly due to the difference in the electronegativity of the oxygen and hydrogen atoms and the water molecule possesses an electric dipole moment of 1.85 Debye (Franks [1973](#); Chaplin [2009](#)).

Each of the two lone pairs of electrons of the oxygen atom and each of the two hydrogen atoms can be involved in a ► [hydrogen bond](#). Every water molecule can therefore be H-bonded with up to four other water molecules. Although hydrogen bonding is a relatively weak attraction compared to the covalent bonds within the water molecule itself, the hydrogen bonds that form between water molecules account for some of the unique properties of water in the condensed phase, such as its high cohesion energy density, its high surface tension, and its relatively high melting and boiling points. The extensive hydrogen-bonding network between the molecules also gives liquid water a large specific heat capacity (Franks [1973](#)).

Solid water (ice) can form, depending on the pressure and temperature, 1 of 15 known phases that are differentiated by their crystalline structure, ordering, and density. There are also

two metastable phases of ice under pressure (Salzmann et al. 2006).

Water molecules can interact efficiently with anions via hydrogen bonds and with cations via coordination between the lone pairs on the oxygen atom and empty orbitals of the cations. Polar species are also highly soluble in water. The poor solubility of apolar compounds in liquid water, described as “hydrophobicity,” is a direct consequence of the fact that water molecules form an infinite and dynamic network of hydrogen bonds in the liquid phase (Tanford 1980). Frank and Evans (1945) proposed a simple molecular interpretation for the poor solubility of apolar compounds in water. Their model, which is still generally accepted, suggests that the water structure is strengthened in the first hydration shell around an apolar solute (“hydrophobic hydration”) and explains the unusually large entropy loss encountered upon dissolution of a nonpolar compound in water. This term more than compensates the favorable enthalpy change, and consequently the transfer of an apolar solute from the gas phase (or from a nonpolar medium like its pure liquid phase) to a dilute water solution is characterized by a large and positive free-energy change.

The term “hydrophobic interaction” is commonly used to describe the interaction between nonpolar solutes in water (Ben-Naim 1980, 2002; Chandler 2005). The association of the nonpolar solutes in water is accompanied by a decrease of the entropy of the interacting partners which is overcompensated by an increase of the entropy of the water molecules as the total hydrophobic surface that the bimolecular, or polymolecular, complex offers to the water molecules is lower than the sum of the surfaces offered by the separated partners. Therefore, there is an global increase of entropy associated to the binding event linked to the dehydration of the apolar surfaces that are buried in the complex.

The Origin of Liquid Water on Earth

Until now, liquid water has only been found on Earth. It is highly unlikely that liquid water exists on the surface of any other body of our Solar System, but if it is present elsewhere in the Solar System, it could be present in the Martian

subsurface or below the icy crust of a Jovian satellite like Europa. Water vapor and solid water (ice) are of course abundant in the Solar System. Water vapor is present in the atmosphere of many planets and comets are described as “dirty snowballs.” Water is also present in the form of crystallization water in the mineral matrices of a class of meteorites called carbonaceous chondrites, which, in some cases, have a water content higher than 20% by weight.

The origin of water on Earth remains a subject of debate (Gargaud et al. 2001). It has been suggested that the young Earth was essentially formed by the accretion of planetesimals with a low water content. According to this scenario, water on Earth is the result of post-accretion delivery involving the impact of asteroids, meteorites, micrometeorites, and comets coming from the external parts of the Solar System that had a high water content. The young Earth, just after accretion, is described as a “hot and dry” body, heavily bombarded by large impactors. After this dramatic event, the bombardment by massive bodies was slowly replaced by a very important flux of micrometeorites characterized by a high content of volatiles like dinitrogen, carbon dioxide, and water.

Another scenario, called the endogenous scenario, is sometimes also evoked to explain the origin of liquid water on the Earth’s surface. It is associated with the degassing of the Earth’s crust and mantle. Even if this scenario is currently considered to be less plausible than the exogenous scenario, this does not exclude the possibility that a certain percentage of the water present on the surface of the young Earth was the result of the violent volcanism which was certainly taking place during the first hundreds of million years after the Earth’s formation. This endogenous scenario implies that the young Earth already had a non-negligible water content and therefore that planetesimals coming from the external part of the Solar System must have contributed to the first phase of the accretion.

Initially, water on the Earth was present as crystallization water in rocks or as water vapor in the atmosphere as the temperature and pressure conditions were incompatible with the existence of liquid water. Just after accretion the Earth was a

hot body but the cooling by radiative processes was very efficient and, after a few tens of million years, the solid crust was formed. Subsequently, various post-accretion phenomena took place and an atmosphere slowly surrounded the lithosphere. The radiative heat transfer between the hot planet and outer space was such that it can be estimated that the surface temperature of the young Earth would have quickly reached values too low for liquid water to be able to accumulate. Furthermore, the young Sun in its T-Tauri phase was most probably a “pale Sun” with a less intense electromagnetic spectrum than today at least in the near-UV/visible region of the spectrum (the amount of X-rays was probably much higher than today) (Gargaud et al. 2001). The light intensity in the near-UV/visible range was probably 25% lower than the present value. The only way to explain how liquid water managed to accumulate, and to solve what is often called the “faint solar paradox,” is to imagine the presence of an intense greenhouse effect, much more efficient than what occurs today (Sagan and Chyba 1997). An atmospheric pressure of few bars of carbon dioxide is one hypothesis to solve this paradox and explain how liquid water was present on the Earth’s surface 4.4 Gy ago (Gargaud et al. 2001). The presence of sedimentary rocks 4 Gy old and the existence of zircons, which seem to be 4.4 Gy old, are evidence suggesting that the oceans formed 4.4–4 Gy ago. This date gives the upper limit for what is frequently considered as the first steps of the process leading from non-living to living matter.

The Role of Water in Prebiotic Evolution

Today, the presence of life on Earth depends on the availability of liquid water. In living systems, water is ubiquitous and cannot be considered merely a diluent. It performs many functions: it transports, structures, stabilizes, lubricates, reacts, and partitions. It is widely appreciated that water molecules play an invaluable role in governing the structure, stability, dynamics, and function of important biomolecules such as proteins and nucleic acids (Ball 2008). Molecular water also plays a key role in the formation of the

association complexes (Ben-Naim 2002) and entropy-driven binding processes, as discussed above is a phenomenon widely encountered in molecular biology and plays a role in many processes of major importance in the living world. The finely tuned involvement of water in life processes is confirmed by the fact that heavy water is toxic to these processes in many organisms, although some microbes are able to tolerate almost complete isotopic substitution. Liquid water is a component of all living cells and its role is so important and fundamental that it is difficult to imagine any form of life without liquid water (Bruylants et al. 2010; Locci et al. 2002).

Research devoted to the processes by which matter evolved from “nonliving” to “living” must take into account the role of water. It seems impossible to imagine any primitive form of life in the absence of liquid water but, on the other hand, the possibility that life forms without DNA or proteins is conceivable; the “RNA world” being one example (Orgel 2004). In a way, water appears more important than DNA or proteins for prebiotic evolution!

The spontaneous formation of membranes may be one of the first steps in prebiotic evolution, not only because it separates an “in” and an “out” but also because membranes represent an apolar medium in which condensation reactions can take place (Luisi et al. 1999; Ourisson and Nakatani 1996). In water, the spontaneous formation of vesicles or liposomes is a well-known process governed by the entropy increase of water upon desolvation of hydrophobic surfaces. This suggests that, without liquid water, life based on cells separated from the external world by organic membranes could never have appeared on Earth.

The living world should be thought of as an equal partnership between proteins, nucleic acids, lipids, ions, and water. No other molecule abundant on the primitive Earth and abundant in the Solar System could have played this role. It is even highly probable that any other form of life in the universe, if it exists, is based on liquid water.

H₂O

Definition

The electromagnetic spectrum of H₂O contains three different types of transitions, electronic (optical-ultraviolet), vibrational (infrared), and rotational (millimeter, submillimeter, far-infrared). Ro-vibrational transitions occur between the rotational levels of different vibrational modes.

Overview

Water vapor, as all molecules, has rotational transitions, in which the rotational angular momentum changes following allowed selection rules, and vibrational transitions in which the nuclei of the molecule change their distance following the fundamental vibrational modes of the molecule. In addition, H₂O has also electronic transitions related to the movement of the electrons.

Pure rotational transitions of water vapor fall in the millimeter, submillimeter, and far-infrared domains, while vibrational transitions fall in the infrared domain of the electromagnetic spectrum. As H₂O is a light species, most of its rotational transitions are in the far-IR domain.

The observation of water vapor from ground-based observatories is practically impossible due to the strong telluric absorption produced in our

own atmosphere (see Cernicharo et al. 1990, for details on atmospheric transmission at mm and submm wavelengths for water vapor lines). Only after the launch of the ► [Infrared Space Observatory](#) it was possible to study the full rotational spectrum of water vapor in the far infrared (Cernicharo and Crovisier 2005).

The fundamental vibrational modes of water vapor ν_1 (symmetric stretching), ν_2 (bending mode), and ν_3 (antisymmetric stretching) occur at 3,657, 1,595, and 3,756 cm^{-1} , respectively (2.73, 6.27, and 2.66 mm). The rotation of the molecule is coupled to its vibration producing ro-vibrational bands with well-defined absorption features that can be even resolved at medium spectral resolution. The observation of these

bands toward astronomical objects was also possible with the Infrared Space Observatory (van Dishoeck et al. 1998; González-Alfonso et al. 1998; González-Alfonso et al. 2002). The role of infrared pumping in the intensity of the rotational lines of H_2O was discussed in detail by González-Alfonso and Cernicharo (1999) (Fig. 1).

The Herschel satellite has provided high spectral resolution of H_2O rotational lines permitting the study of the water abundance with unprecedented sensitivity in a large variety of molecular clouds, evolved stars, solar system bodies, protoplanetary disks, and galaxies (see, e.g., van Dishoeck et al. 2014, 2021; Alcolea et al. 2013; Bockelée-Morvan et al. 2012; Podio et al. 2013; González-Alfonso et al. 2012; Yang et al. 2013).

Water, Vibrational and Rotational Transitions, Fig. 1 Rotational levels of ortho and para water up to energies of 2,000 K. The rotational transitions indicated by arrows correspond to some of the maser lines observed from ground-based observatories. The two species of water vapor, ortho and para, result from the different projection of the spin of the two identical hydrogen atoms in the molecule with statistical weights 3:1 (ortho corresponds

to parallel spins, para to antiparallel spins). Under the physical conditions of the interstellar medium, the only way to transform ortho into para species is through reactions with protons. Hence, both species have to be considered as independent molecules having a different energy level structure and different frequencies for their rotational transitions

H₂O Observations from Ground-Based Observatories

Only a few transitions of H₂O having maser character have been observed from the ground, allowing in particular for the detection of H₂O for the first time in 1969 at 22 GHz through its $6_{16}-5_{23}$ rotational transition at 22.235 GHz (Cheung et al. 1969). The size of the emitting regions at this frequency is typically of the order of a few milliarcseconds (a few 10^{13} cm at the distance of Orion). Hence, no information has been obtained from ground-based observations on the role of water vapor at large spatial scales from this line. Other H₂O lines have been detected from ground- or airborne-based telescopes like the $3_{13}-2_{20}$ transition at 183 GHz (Waters et al. 1980; Cernicharo et al. 1990, 1994), the $4_{14}-3_{21}$ transition at 380 GHz (Phillips et al. 1980), the $10_{29}-9_{36}$ transition at 321 GHz (Menten and Melnick 1991), and the $5_{15}-4_{22}$ transition at 325 GHz (Menten et al. 1990; Cernicharo et al. 1999). All these lines have been detected toward interstellar and circumstellar molecular clouds. Other lines of H₂O between 400 and 500 GHz have been observed toward evolved stars with the APEX telescope (Menten et al. 2008).

Among these lines, only the $3_{13}-2_{20}$ transition at 183 GHz, for which the terrestrial atmosphere can be partially transparent under excellent weather conditions, has been used to map the emission of water at very large spatial scales (Cernicharo et al. 1994). As an example, the extent of water vapor from the map of the Orion molecular cloud shown in Cernicharo et al. (1994) is six orders of magnitude larger than the size of the spots detected at 22.235 GHz.

Watson-Crick Pairing

Henderson James Cleaves II
 Earth-Life Science Institute (ELSI), Tokyo
 Institute of Technology, Tokyo, Japan
 Blue Marble Space Institute of Science,
 Washington, DC, USA
 Center for Chemical Evolution, Georgia Institute
 of Technology, Atlanta, GA, USA

Definition

In molecular biology, two nucleotides on complementary DNA or RNA strands that are connected via hydrogen bonds are called a base pair. In canonical Watson-Crick base pairing in DNA, adenine (A) forms a base pair with thymine (T) using two hydrogen bonds, and guanine (G) forms a base pair with cytosine (C) using three hydrogen bonds. In canonical Watson-Crick base pairing in RNA, thymine is replaced by uracil (U). The name of this

type of base-pairing derives from the names of two of the co-discoverers of the molecular structure of DNA, James Watson and Francis Crick. DNA with high GC content is more stable to denaturation or melting than DNA with low GC content. Watson-Crick base pairing is also the mechanism by which mRNA codons are recognized by anticodons on tRNA molecules during protein translation.

The purine nucleobases, adenine and guanine, are double-ringed molecules. The pyrimidine nucleobases, cytosine, uracil and thymine, are single-ringed molecules. In Watson-Crick base pairing, purines are only complementary with pyrimidines, partly due to the distance between the hydrogen-bonding surfaces and the nucleic acid backbone. GT and AC mispairings are unfavorable because the pattern of hydrogen donors and acceptors does not correspond structurally. Alternative hydrogen-bonding schemes, such as wobble base pairing and Hoogsteen base pairing, also occur, particularly in RNA, giving rise to complex and functional tertiary structures.

Wave Number

José Cernicharo Quintanilla
 Laboratory of Molecular Astrophysics,
 IFF-CSIC, Madrid, Spain

Definition

In certain molecular spectroscopies, the frequency of electromagnetic radiation is measured in units

of cm^{-1} , known as wave numbers. It corresponds to the inverse of the wavelength of the electromagnetic wave. The conversion factor between frequencies in MHz and frequencies in wave numbers is $1 \text{ cm}^{-1} = 29,979.2458 \text{ MHz}$. The wave number is also used as an energy unit. A photon of frequency ω wave numbers carries an energy of $\approx 2 \cdot 10^{-17} \omega \text{ erg} \approx 1.22 \cdot 10^{-5} \omega \text{ eV} \approx 1.43 \omega \text{ K}$.

Wavelength

José Cernicharo Quintanilla
Laboratory of Molecular Astrophysics,
IFF-CSIC, Madrid, Spain

Definition

The wavelength of a signal is defined as the distance between two consecutive intensity

maxima (or minima) and corresponds to its spatial period (see Fig. 1). It is denoted by the Greek symbol lambda (λ). For an electromagnetic wave propagating in the vacuum, the wavelength is related to the frequency through the relation $\lambda = c/v$, where c is the speed of light ($299792.458 \text{ km s}^{-1}$) and v the frequency of the signal. The electromagnetic spectrum is divided in different ranges depending on the frequency of the photons (energy = $h\nu$, where h is the Planck constant; see Table 1; see also astrobiological data). Most media broadcasts use radiation in the radio domain. The rotation of molecules emits in the millimeter and sub-millimeter domains. Molecular vibrations produce emission in the far-, mid-, and near-infrared domains. Emission due to orbital changes of electrons in atoms and molecules occurs in the optical and ultraviolet domains. Nuclear changes produce emission in the extreme ultraviolet and X-ray domains. Each of these wavelength ranges corresponds to a specific branch of astrophysics for which specific instruments and technologies are developed.

Wavelength,

Weak Bonds

Jun-ichi Takahashi
Faculty of Engineering, Yokohama National
University, Yokohama, Japan

Definition

Weak chemical bonds are those forces of attraction that, in biological situations, do not take a large amount of energy to break. For example, hydrogen bonds are broken by energies in the order of 4–5 kcal/mol and van der Waals interactions have energies around 1 kcal/mol. In biological terms, ionic bonds, hydrogen bonds, and van der Waals interactions are considered weak bonds. In biological systems, weak bonds are being continually broken and reformed without the aid of enzymes. Weak bonds may be easily broken, but they are very important because they help to determine and stabilize the shapes of biological molecules. For example, they are important in stabilizing the secondary structure (alpha helix

and beta-pleated sheet) of proteins. Hydrogen bonds keep complementary strands of DNA together. Hydrogen bonds participate in enzymic catalysis.

Weathering

Nicholas Arndt
Emeritus Professor, ISTERre, University Grenoble
Alpes, Grenoble, France

Definition

Weathering refers to the processes by which the rocky surface of the Earth is subjected to physical disintegration and chemical decomposition when

exposed to atmospheric or water-related agents. During weathering, rocks change color, texture, chemical and mineralogical composition, firmness, and/or form, with little or no transport of the loosened or altered material. Mineral and rock debris will constitute the skeleton of clastic sediments (i.e., sands), and through diagenesis, clastic sedimentary rocks (breccia, sandstone, etc.). The action of water and oxidizing conditions destabilizes high-temperature minerals such as ► [olivine](#), pyroxene, or plagioclase, converting them to low-temperature secondary minerals, mainly clays and iron oxides. In this process, the rock is converted partially or completely from hard solid material, commonly with large interlocking crystals, to soft, unconsolidated, hydrous, fine-grained material that is then subject to mechanical erosion. Two types of weathering can be distinguished: Mechanical weathering involves breakdown of the mineral or rock structure by the physical action of heat, water, or ice or by asteroidal impact. Chemical weathering entails the chemical breakdown of thermodynamically unstable minerals, usually in the presence of water. A typical product of mechanical weathering is ► [planetary regolith](#) and ► [terrestrial regolith](#), while clay minerals are a typical product of chemical weathering of silicate minerals.

Weathering Profile

Daniele L. Pinti
Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Synonyms

[Alteration profile](#)

Definition

A weathering profile is a vertical assemblage of weathering zones (subsurface zones of alteration differing physically, chemically, or mineralogically from adjacent zones) from the unaltered bedrock to the surface soil. The nature of the weathering profile is a complex response to climatic and geologic controls and to long-term changes in surface environmental conditions. In modern Earth, weathering profiles are best developed at the equator (lateritic soils), where depths of 30 up to 100 m are found. Astrobiologists study paleo-weathering profiles (or paleosols) because their mineralogical and geochemical characteristics give constraints on the redox state of the atmosphere of early Earth.

White dwarfs

Synonyms

Degenerate stars

Acronyms

WD	White dwarf
Ga	Giga-annum (10^9 years)
SDSS	Sloan Digital Sky Survey
SCSS	SuperCOSMOS Sky Survey

Definition

White dwarfs are the final outcome of low and intermediate mass stars. Because of the electron degeneracy they cannot ignite their nuclear fuel and their destiny is to cool down forever if they are single. On the contrary, if they are members of a close binary system they can interact with the companion and give rise to a plethora of astronomical phenomena or objects like novae, supernovae, or cataclysmic variables.

History

The first white dwarf, 40 Eridanus B, was discovered by Friederich Wilhelm Herschel in 1785, and the second one, Sirius B, by Alvan G. Clark, in 1862, both as members of a stellar binary system. The third one, the Van Manneken's Star, was discovered in 1917 and was a single star. Since then, the number of known white dwarfs has been steadily increasing thanks to different cosmological surveys (Rowell and Hambly 2011; Kleinman et al. 2013; Kepler et al. 2016) and the Gaia mission (Gentile Fusillo et al. 2019). At present the total number of known white dwarfs is near $\sim 300,000$ and this figure is expected to increase by two orders of magnitude when the Vera C. Rubin Observatory will be operating. A detailed description of how the understanding of these stars has evolved with time can be found in H. M. Van Horn (2015).

Overview

White dwarfs are the final outcome of the evolution of low and intermediate mass stars, those with a mass smaller than 8–9 solar masses. Their mass lies in the range of 0.15–1.35 solar masses, although the majority have a mass between 0.5 and 0.7 solar masses, being the average of the order of 0.6 solar masses. The size of these stars is of the order of the size of the Earth, which implies an average density of 10^6 g cm^{-3} . Their structure consists of a degenerate core that contains about the 98% of the mass of the star and a thin non-degenerate envelope.

In the majority of cases, this core is made of a mixture of ^{12}C and ^{16}O , with a distribution that depends on the mass and chemical composition of the parent star, plus a small amount of inherited metals. Some of them are in the form of ^{22}Ne , which is synthesized during the hydrogen and helium burning stages from the initial content in carbon, nitrogen, and oxygen. White dwarfs with a mass smaller than ~ 0.4 solar masses are made of helium, and those with a mass larger than ~ 1.05 solar masses are made of oxygen and neon. Helium white dwarfs can only be the outcome of the evolution of a binary system, and at least a fraction of the massive ones are the outcome of the merging of two degenerate stars in a binary system.

The structure and properties of white dwarfs are essentially determined by the equation of state of degenerate electrons (Chandrasekhar 1939) and, consequently, they cannot obtain energy from thermonuclear reactions. This means that in the case of single white dwarfs their evolution is just a cooling process in which the initially hot core provides the energy and the outer layers control the energy outflow. As it can be seen from Fig. 1, they span over a wide range of luminosities, from 10^3 to 10^{-4} times the solar luminosity, and temperatures, from nearly 200,000 K to less than 4,000 K. A simple calculation shows that this evolution is very long, since it takes more than 10 Ga to cool down from the planetary nebula stage to the present limit of detectability.

The transition from an AGB star to a white dwarf is not well known at present. Fortunately, white dwarfs are very hot at this epoch and neutrinos dominate the cooling (Fig. 1). As a consequence, all the initial thermal structures converge to a unique one when the luminosity reaches the value of $\sim 10^{-1.5}$ solar luminosities. This stage is very short, less than 10^8 years, and does not introduce severe distortions in the calculation of the age of the star. Within the luminosity interval of $10^{-1.5}$ – 10^{-3} solar luminosities, the equation of

state of the interior is that of a Coulomb liquid, the behavior of the star is relatively simple, and all the existing theoretical models are concordant.

When luminosities are of the order of 10^{-3} solar luminosities, the exact value depends on the mass of the white dwarf, the plasma starts to crystallize and, because of the differences of solubility between the liquid and the solid phases, an oxygen-rich core surrounded by a carbon-rich mantle forms, a structure that is similar to the existing one in the Earth interior (see Fig. 2). This process implies a release of gravitational energy that can maintain the star warm for an additional period of time (Mochkovitch 1983). The presence of impurities like ^{22}Ne reinforces this effect and introduces additional time delays (Isern et al. 1991, 1998). When almost all the star has solidified, the specific heat follows the Debye’s law, the heat capacity is strongly reduced, and the star quickly fades.

In all cases, there is a thin helium layer of 10^{-2} – 10^{-4} solar masses surrounding the white dwarf core. This mantle, in turn, is itself surrounded by a layer made of pure hydrogen, which has a mass in the range of 10^{-4} – 10^{-12} solar masses, and can be absent in the $\sim 25\%$ of individuals. From the phenomenological point of

White Dwarf, Fig. 1 Evolution of a typical white dwarf in the Hertzsprung-Russell diagram

White Dwarf, Fig. 2 Structure of a white dwarf during the crystallization process

view, white dwarfs showing hydrogen in their spectra are named DA, while the remaining ones (the non-DA) are classified, in order of decreasing temperatures, as DO, DB, DQ, DZ, and DC depending on their spectral features. There are also some exotic objects, with anomalous compositions, that are suspected to be the outcome of the merging of two white dwarfs.

The evolution of the envelope is rather complicated (Fig. 3) and is a consequence of (i) a nonstandard initial chemical composition resulting from the evolution of AGB stars, (ii) a very efficient gravitational settling that induces the stratification of the envelope with the lightest element in the top (Schatzman 1958), and (iii) the action of different mechanisms that tend to restore the homogeneity like convective mixing, radiative levitation, thermal diffusion, accretion from the interstellar medium, and winds (Althaus et al. 2010; Fontaine et al. 2013).

The character DA, non-DA is linked to the origin of the white dwarf itself and can change along their evolution. DAs are born with a variety of H-layer masses. When they are hot, radiative levitation brings heavy elements to the surface, but as soon as the temperature drops, they settle down and disappear from the spectrum. When the temperature is low enough, convection appears in the envelope and the hydrogen layer mixes with the helium mantle. The DA white dwarf becomes

a non-DA, being those with thinner layers the first ones to do the transition.

The evolution of non-DAs is more complicated. They are the descendants of He-rich planetary nebulae or the result of a merger episode. Their envelope is mainly made of helium with some traces of hydrogen that gradually floats to the surface and forms a thin hydrogen layer that grows with time. At the beginning of this cooling process, they look as DO stars but when the temperature becomes of the order of $\sim 50,000$ K the hydrogen layer becomes thick enough to hide the helium mantle and the white dwarf appears as a DA. When the temperature drops below 30,000 K, the helium layer becomes convective, it engulfs the hydrogen layer and the white dwarf becomes a non-DA once more, more precisely, a DB white dwarf. The lack of non-DA white dwarfs in the temperature range of 45,000–30,000 K is known as the DB-gap. Further cooling converts them into DZ and DC white dwarfs, the last ones being partially DAs in origin.

Basic Methodology

There are two important tools to confront theory with observations: the luminosity function and the seismological properties.

White Dwarf,

Fig. 3 Physical mechanisms operating in the envelope of white dwarfs

During their evolution, white dwarfs experience instabilities that cause periodic fluctuations in their luminosities and offer the possibility to analyze their interior (Cox 1980). These fluctuations are generated by global non-radial pulsations driven by buoyancy in the gravity field of the star (the so-called g-modes). These pulsations have typical amplitudes in the range of 0.1 mag to 0.4 mag and periods in the range of 100–7000 s. Although new divisions have recently appeared as a consequence of the spectacular improvement of the observational background, they are classified as: (i) DAVs or ZZ Ceti stars with temperatures and gravities in the range of 10,400–12,400 K and $\log g$ (cm^2s^{-1}) in the range of 7.5–9.1, respectively, and a hydrogen dominated atmosphere, (ii) DBVs or V777 Her stars with temperatures and gravities in the domain of 22,400–32,000 K and $\log g$ in the range of 7.5–8.3, respectively, and a helium-dominated atmosphere, (iii) DOV or GW Vir variables with temperatures and gravities in the range of 80,000 and 180,000 K and $\log g$ in the range of 5.5–7.5, respectively. See Córscico et al. 2019, Córscico 2020, and references there in for more information.

In contrast with the Sun and red giants, these pulsations are not induced by convection but by a mechanism related with the behavior of opacity in the partially ionized zones. The still existing uncertainties do not prevent to obtain information about the star. For instance, it has been possible to determine the mass and the internal stratification of several variables (Gianmichele et al. 2018; Bischoff-Kim et al. 2019; Córscico et al. 2019) or the cooling rate via the secular drift of the pulsation period ($dP/dt \sim 10^{-15} \text{ s}^{-1}$ in the case of the ZZ Ceti stars, as detected for the first time by Kepler et al. 1991).

The luminosity function is defined as the number density of white dwarfs of a given luminosity per unit of magnitude interval, i.e., the distribution in luminosity of white dwarfs along the cooling track (Weidemann 1968; Garcia-Berro and Oswalt 2016). Figure 4 displays the shape of this function obtained with the data provided by the SDSS and SCSS catalogues. The first noticeable property is the monotonic increase of the number of white dwarfs with the magnitude followed by a

shortfall of dim stars. This confirms that the evolution of these stars is just a simple gravothermal process of cooling since, on the one hand, low temperature stars accumulate because they cool down more slowly than the hot ones (Mestel 1952) and, on the other hand, they cannot reach an arbitrarily low temperature as a consequence of the finite age of the Galaxy (Winget et al. 1987).

Key Research Findings

The most important results recently found are the confirmation of the stratified structure of the interiors as well as the role played by crystallization and the associated sedimentation of the internal layers. These improvements in the understanding of the evolution of white dwarfs have allowed to reconstruct, at least in part, the star formation history of the solar neighborhood.

Applications

A relevant application for Astrobiology is the determination of the bulk composition of rocky planets based on the observation of metal features in the spectra of cool white dwarfs (Jura and Young 2014). Since the time scale for sinking of elements heavier than helium is much smaller than the cooling age of white dwarfs it must be concluded that these metals have been accreted from the nearby circumstellar medium. At present it is widely accepted that this pollutant material comes from the remnants of the planetary system that was accompanying the parent star. Dynamical instabilities, planetesimal scattering, and tidal disruption led to the formation of an accretion disc from which matter is accreted to the white dwarf (Veras 2016). However, in order to extract the information provided by the spectra it is necessary to improve the models of atmosphere of white dwarfs as well as the diffusion mechanisms in such environments. The first results suggest that the geological properties of the Solar System are not uncommon in the Galaxy.

Another important application of white dwarfs is their ability for testing new ideas in Physics.

White Dwarf, Fig. 4 Luminosity functions obtained from the SDSS catalogue: Black solid squares (Harris et al. 2006). Blue crosses (Krziesinski et al. 2009). Magenta stars were obtained from the SCSS catalogue (Rowell and

Hambly 2011). Red triangles are from Legget et al. (1998). All of them contain DA and non-DA stars. Open black squares, only contain DAs (DeGennaro et al. 2008)

Very often nonstandard theories predict the existence of new particles or new phenomena that cannot be tested in terrestrial laboratories due to the energies involved. One way to alleviate the problem is to examine the perturbations they introduce in the normal evolution of stars (Raffelt 1996). Since the evolution of white dwarfs is a relatively simple process of cooling and the basic ingredients of their evolution are well identified they can be used for this purpose (Isern and Garcia-Berro 2008). In particular, just to cite few examples, white dwarfs have provided bounds to the mass of axions, to the secular drift of the Newton gravitational constant or to the density of magnetic monopoles.

Future Directions

Gaia and the cosmological surveys have provided an unprecedented and large set of accurate

photometric and astrometric data that are revolutionizing the existing ideas about white dwarfs and their role in the Galaxy. Unfortunately, an equivalent set of spectroscopic data is still lacking in order to determine their masses, their detailed chemical composition, the incidence of magnetism among them, or the nature of the mechanism that excites and quenches their pulsations, but projects like WEAVE or DESI and others will overcome this problem quite soon and will provide a deep insight on their nature.

Wobble Hypothesis (Genetics)

Juli Peretó
Institut Cavanilles de Biodiversitat i Biologia
Evolutiva, Universitat de València, València,
Spain

Definition

The Wobble hypothesis proposes that normal base pairing can occur between nitrogen bases in positions 1 and 2 of the codon and the corresponding bases (3 and 2) in the anticodon. Actually, the base 1 in anticodon can form non-Watson-Crick base pairing with the third position of the codon. The hypothesis is applicable to most (not all) tRNAs.

History

Hypothesis proposed by Francis Crick in 1966 to explain the observed degeneracy in the third position of a codon.

Wobble Pair

Henderson James Cleaves
Earth-Life Science Institute (ELSI), Tokyo
Institute of Technology, Tokyo, Japan
Blue Marble Space Institute of Science,
Washington, DC, USA
Center for Chemical Evolution, Georgia Institute
of Technology, Atlanta, GA, USA

Definition

A wobble pair, or wobble-base pair, is a hydrogen-bonded pairing between two ► [nucleotides](#) generally occurring between two RNA molecules. These base pairs are geometrically distinct from the canonical Watson–Crick-type base-pairing. The main wobble base pairs are hypoxanthine-uracil (I-U, where I represents inosine, the nucleoside formed from hypoxanthine), guanine-uracil (G-U), hypoxanthine-adenine (I-A), and hypoxanthine-cytosine (I-C). Wobble base pairs are of comparable thermodynamic stability to Watson–Crick base pairs. Wobble base pairs occur frequently in RNA secondary structure and are important for proper translation of the genetic code.

In 1966, Francis Crick proposed the Wobble hypothesis to account for the fact that most organisms do not seem to have as many tRNA molecules as would be required for complete translation of the genetic code. There are 64 possible codons in the

genetic code. During translation, each of these codons requires a tRNA molecule with a complementary anticodon to bring the appropriately charged amino acid into position on the ribosomal-mRNA complex. If each tRNA molecule paired only with its exactly complementary mRNA codon via Watson–Crick base-pairing, then 61 types of tRNA would be required (64 codons minus the 3 used as stop codons). Since most organisms have less than 45 distinct tRNA types, some tRNAs pair with more than 1 codon. The means by which this pairing promiscuity is achieved is via the use of wobble pairs formed between tRNA/mRNA complexes.

Woese, Carl

Stéphane Tirard

Centre François Viète d'Histoire des Sciences et des Techniques EA 1161, Faculté des Sciences et des Techniques de Nantes, Nantes, France

Carl Woese was an American microbiologist, born in New York in 1928. In 1977, he discovered the third lineage among the living beings, the Archaeas, which are microscopical entities, beside eukaryotes and prokaryotes. This discovery was based on the comparison of RNA sequences, showing that Archaea are no more close to prokaryotes than to eukaryotes.

This discovery constituted a fundamental transformation of the conception of the microscopical world and of the classification of living beings.

X

X-Rays (Organic Synthesis)

Jun-ichi Takahashi
Faculty of Engineering, Yokohama National
University, Yokohama, Japan

Definition

An X-ray is a form of electromagnetic radiation having a wavelength in the range of 0.01–10 nm, corresponding to energies in the range 120 eV–120 keV. These ranges are intermediate between vacuum ultraviolet light and gamma rays. Neutron stars, white dwarf stars, supernova remnants, cluster of galaxies, and black holes in active galaxy nuclei are sources of intense X-rays. X-rays and cosmic rays may be implicated in the prebiotic formation of organic compounds in the primitive Earth atmosphere.

Overview

From the standpoint of astrobiology, it has been proposed that electromagnetic radiation or cosmic rays are the effective energy sources for synthesizing the precursors of terrestrial organic compounds in the primitive Earth environment. Experiments designed to verify this hypothesis

have been conducted using photon beams from synchrotron-radiation light sources and proton, ion, or electron beams from high-energy particle accelerators, simulating electromagnetic radiation and cosmic rays from extraterrestrial circumstances. Small inorganic molecules in the primitive Earth atmosphere, especially nitrogen and carbon monoxide, are not readily decomposed by ultraviolet irradiation. Bond energies of nitrogen and carbon monoxide are 9.76 and 11.09 eV, respectively, corresponding to the photon energy of vacuum ultraviolet light. Higher-energy photons from the vacuum ultraviolet to X-ray region are therefore required for direct photolysis and to trigger the subsequent chemical processes that synthesize organic compounds.

Takahashi et al. (1999) simulated the process using 1–2 keV X-ray irradiation from a synchrotron source on a mixture of carbon monoxide, nitrogen, and water that represents the primitive Earth atmosphere. In the hydrolyzed product, several kinds of amino acids were detected by high-performance liquid ► [chromatography](#). The amount of glycine and alanine increased with the total energy absorbed by the gas molecules. The G-value (number of produced molecules per 100 eV absorbed energy) of the glycine production was 0.004, which was smaller than that of the proton beam irradiation by one order of magnitude. The antipodal optical isomers of alanine

were generated in almost equal quantities. The results show that the precursors for amino acids can be produced through X-ray-induced photolysis of inorganic molecules followed by synthesis into organic compounds. The X-ray irradiation effects can be attributed to two reaction schemes: (1) photochemical reactions preceded by core-level electronic excitation of the molecules and (2) radiation chemical reactions preceded by secondary electron generation.

[Radiation](#)

Definition

In astronomy, the term “X-rays” corresponds to high-energy radiation seen in the 0.1–10 keV range. Among celestial bodies, all types of stars emit X-rays, with the exception of A-type stars (mass $\sim 2 M_{\odot}$, where $M_{\odot}$ is for one solar mass, effective temperature $\sim 10,000$ K on the main sequence). In terms of internal structure, A stars are at the boundary between “late-type,” cooler, lower-mass stars (equivalently “solar-type” stars), which have an outer convective zone and an inner radiative zone, and “early type,” hotter, higher-mass stars, which have a convective core and an outer radiative zone. Cool stars emit X-rays as a result of reconnection of magnetic fields generated by the dynamo effect in their outer convective zone, while hot stars emit X-rays as a result of shocks in the winds accelerated by radiation.

Overview

Stellar X-ray emission is ubiquitous: nearly all stars show some form of activity which translates into X-ray emission at some level. The X-ray emission mechanism is “thermal,” i.e., ► [bremsstrahlung radiation](#) is produced by gas heated to $\sim 10^6$ – 10^7 K mainly in two ways, depending on the nature of the stellar outer layers. In cool stars, the path to X-ray emission follows several steps, lasting several hours from beginning to end: convection → dynamo effect → surface magnetic fields → reconnection of magnetic field lines of opposite polarity → gas heating to million degrees → X-ray emission (flares) → cooling.

In hot (massive) stars, in general, magnetic fields are not involved, because the outer layers of hot stars are radiative, i.e., they are in stable gravitational equilibrium. However, radiation exerts a force on the atoms, and the uppermost layers, which have a lower density, are pushed away from the star and give rise to a *radiative stellar* wind. The resulting mass loss can be considerable for massive stars (in particular O stars and Wolf-Rayet stars). This is because their effective temperature can be very high (up to 10^5 K), producing a mass loss of $1 M_{\odot}$ in 1 Myr, at velocities reaching several 1000 km/s. But it can be shown that these

stellar winds are “radiatively unstable,” some parts of the wind being temporarily pushed more efficiently than others. This creates shocks within the wind, strong enough to heat parts of the wind to X-ray temperatures. In this case, the mechanism for X-ray emission is quite different from cool stars, as it does not involve magnetic fields. The steps are stellar UV radiation → radiative force → acceleration of heavy atoms → stellar wind (mass loss) → instabilities in the wind → supersonic shocks → sustained X-ray emission.

However, for some stars a “hybrid” mechanism (radiation + magnetic fields) has been found. Indeed, large-scale, stable magnetic fields (“magnetospheres”) have been detected and measured in a few percent of massive, hot stars. The reason is probably that these stars have somehow retained their “primordial” magnetic fields, i.e., the magnetic field built in the clump of interstellar matter that collapsed to form them. These stars have “magnetically confined” winds, with two properties: (1) the fact that the wind is forced to flow along magnetic field lines weakens the radiative instability and (2) in the closed regions of the magnetosphere, the flows from opposite latitudes are forced to converge at large distances from the star and eventually collide against each other, again heating the gas to X-ray temperatures.

This context explains in particular why A stars, which are fully radiative and have no magnetic fields, show no activity and do not emit X-rays.

XANES

Henderson James Cleaves

Earth-Life Science Institute (ELSI), Tokyo
Institute of Technology, Tokyo, Japan
Blue Marble Space Institute of Science,
Washington, DC, USA

Georgia Institute of Technology, Center for
Chemical Evolution, Atlanta, GA, USA

Synonyms

[X-ray absorption near-edge structure](#)

Definition

XANES is a form of atomic adsorption spectroscopy used in chemical analysis. XANES can be used to determine a great deal of chemical information, for example, the formal valence of an atom and its coordination environment. XANES spectra can be used as a probe of the unoccupied band structure of a material. The near-edge structure is characteristic of environment and valence state. In a sample containing a mixture of sites or compounds, the measured spectra can be fit with linear combinations of XANES spectra of known species, and the proportion of each in the sample can be determined. Since X-ray absorption edges of light elements such as C, N, and O are located in soft X-ray region, analysis often must be conducted under high vacuum conditions. This technique has been applied to the characterization of meteoritic organics together with STXM (scanning transmission X-ray microscopy).

Xanthine, Fig. 1 Molecular structure of xanthine

Chemical Formula

Definition

Xanthine is one of the purine bases, which is widely distributed in the terrestrial biological system, though it is not included among the canonical five nucleic acid bases. Figure 1 shows a molecular structure of xanthine. Its molecular weight is 152.11. Its nucleoside is xanthosine. It is formed by hydrolysis of guanine or is enzymatically converted from guanine by guanine deaminase. It has been reported that some purine bases and pyrimidine bases including canonical nucleic acid bases existed in extracts from carbonaceous chondrites, but the detected bases have not been the same. Among various purines and pyrimidines, only xanthine was reported to be detected as a major base in Murchison meteorite both by GC/C/MS (Martins et al. 2008) and LC/MS (Callahan et al. 2011).

Yeast

Aldo González

Centro de Biología Molecular, CBMSO Consejo Superior de Investigaciones Científicas
Universidad Autónoma de Madrid, Madrid, Spain

Keywords

Asci · Budding · *Cryptococcus* · Fungi · *Saccharomyces*

Definition

Yeasts are unicellular ► [fungi](#) that in some cases present dimorphism depending on culture media conditions.

Overview

According to recent revisions, yeasts are classified in the kingdom *Mycota*, phylum *Eu-Mycota*. They were included in the class *Endomycota* due to their capacity to form sexual spores in “asci.” In this group, monokaryon spores are released after one meiosis division, and afterward their nuclei could be joined to form dikaryon cells. This process was detected for the first time in this group of microorganisms. In general, their system of reproduction is based on a life cycle that combines firstly reproduction by budding and secondly by

division (binary fission) which is cellular division by simple mitosis and recombination after meiotic reduction. As with filamentous fungi, yeasts are grouped as (1) *Ascomycete*-type yeasts that produce ascospores, (2) *Basidiomycete*-type yeasts that produce basidiospores, and (3) *Deuteromycete*-type yeasts that do not produce sexual spores but have biochemical and/or morphological characteristics, which approximate them to some of the two large groups with complete sexual cycles. *Deuteromycete*-type yeasts follow the same pattern as filamentous fungi, that is, they stay in this group unless they find another sexually compatible cell in nature (mating type). When this event happens, mating occurs, and the zygote is formed. Afterward is the turn of the dikaryon; meiosis takes place which will regenerate the new sexual cycle. To date, more *Ascomycete*-type yeasts than *Basidiomycete*-type yeasts have been identified, mainly because of their importance to the field of nutrition where the genus *Saccharomyces* stands out. In recent years, the pathologies caused by species of *Cryptococcus* in patients with immunodeficiency have given rise to significant advances in the study of those genera that have a complete sexual cycle. Their dependence on a sexual cycle facilitates advances in the genetic and biochemical studies of these microorganisms. Their enormous capacity to reproduce in liquid culture allows experimentation, and the production of the sexual cycle under laboratory conditions allows the genetic manipulation of their

DNA molecules. The systematic classification of the yeasts that do not have well-defined sexual reproduction has led to their systematic classification using only characteristics of asexual reproduction as the basic criterion. Nevertheless, in the special case of yeasts, this asexual reproduction does not present clear morphological differences as is the case for filamentous fungi. For this reason, the taxonomy of this group is based on other aspects such as the structure of cell walls and biochemical criteria. Among the main biochemical tests are their ability to ferment and assimilate hydrocarbons and other compounds. These biochemical criteria contribute to differentiating them into groups. For instance, nitrate assimilation or growth on DBB enables *Asco*- or *Basidiomycete*-type yeasts to be differentiated. Therefore, this classification does not respond to phylogenetic criteria, and the grouping in class, subclass, order, family, genus, and species is merely instrumental. Nowadays, the analysis of DNA sequences (e.g., 18 S rDNA) has provided researchers with an extensive database with which to compare and reorganize their taxonomy at the phylogenetic level and reorder the different groups at the level of genus. To date, approximately 600 species of yeasts have been characterized.

Acronyms

YNP

Definition

Yellowstone National Park is the first US national park, established in 1872. It is located largely in the northwest corner of Wyoming and extending into Montana and Idaho with a total surface area of 8983 km² and includes the Yellowstone Caldera (a caldera is a large crater formed by the collapse of the volcanic edifice after a powerful eruption). The Yellowstone Caldera is considered the largest supervolcano in North America. The Yellowstone National Park has been extensively studied in astrobiology for its many geothermal features, hydrothermal-related mineralization, and the microbial communities that flourish near or within the hot springs.

History

Established by the US Congress and signed into law by President Ulysses S. Grant on March 1, 1872, Yellowstone National Park (YNP) is the first national park in the USA and in the world. Commissioned to the US Army between 1886 and 1916, the administration of the park was passed to the US National Park service in 1917. In 1978, the site of the YNP was named a UNESCO World Heritage Site.

Overview

The Yellowstone National Park (YNP) is the centerpiece of the Greater Yellowstone Ecosystem, the largest remaining nearly intact ecosystem in the Earth's northern temperate zone. Together with its abundant surface hydrothermal

manifestations, nearly 10,000 including 300 geysers, the YNP is one of the best places to study astrobiology and particularly extremophiles microbial communities that flourish near hot springs.

The interest in astrobiology for studying the YNP is dual. First YNP is the site of the largest supervolcano in the North Hemisphere and thus it can be considered a “life killer,” for the consequences that a large super eruption could have had or could have in the future for the life on our planet or in moons and exoplanets where such large eruptions could occur. The second, as above indicated, for studying the numerous geothermal features, which house numerous microbial communities. This volcanic environment could be the natural analogue of early ecosystem on Earth and possibly other planets such as Mars.

YNP is a supervolcano: following the USGS definition, a supervolcano is “a volcanic centre 67 that at one point in time it erupted more than 68 1000 cubic kilometres of material”. For sake of comparison, the Plinian eruption of the Vesuvius of 79 AC that lasted 2 days and destroyed the towns of Pompei and Herculaneum, erupted less than 1 km³ of material. The Yellowstone volcanism is caused by the overriding of the North American plate on a mantle plume, causing the formation of a hotspot, as Hawaii did.

The Yellowstone supervolcano is centered on the Yellowstone caldera, the largest volcanic system in North America. The caldera – a large cauldron-like hollow that forms shortly after the emptying of a magma chamber during cataclysmic volcanic eruptions – was formed by exceptionally large explosive eruptions. Two of the YPN super eruptions are the larger even recorded in geological record and only rivaled by the eruption of the Toba supervolcano in Sumatra, 78,000 years ago. There are two magma chambers under the Yellowstone caldera. The first one is an upper-crustal single magma chamber about 60 km long, 29 km wide, and 5 to 12 km deep. Recently, Huang et al. (2015) have imaged the presence of an even larger and deeper magma chamber (4x in size than the shallower one described above), which connects directly with the mantle plume head.

The current Yellowstone caldera was created by a cataclysmic eruption that occurred 640,000 years ago (the Lava Creek Tuff eruption; Christiansen, 2001), which released more than 1000 km³ of ash, rocks and pyroclastic materials, and created a 1 km deep and 45 to 72 km large caldera depression. Yet, the most violent known eruption occurred 2.1 million years ago, ejecting 2450 km³ of volcanic material and depositing the Huckleberry Ridge Tuff (Christiansen, 2001). A smaller eruption occurred 1.3 million years ago, ejecting 280 km³ of material. Time recurrency of super eruptions in Yellowstone is roughly 600–800 kyrs, alarming authorities on the possibility of a future devastating eruption in North America. Indeed, each of the three climactic eruptions released vast amounts of ash that blanketed much of central North America, falling many thousands of kilometers away. The amount of ash and gases released into the atmosphere probably caused significant impacts to world weather patterns and led to the extinction of some species, primarily in North America.

Major volcanic activity ended 70,000 years ago. Within the YPN area, around 10,000 geothermal features and about two-thirds of the world's geysers are concentrated, likely the largest hydrothermal area in the world. Hydrothermal surface deposits and associated microbial mats and microbial communities of meso- and ► [thermophiles](#) live in the hot and highly mineralized waters of the Great Prismatic Springs. These extremophile communities have been the focus of numerous studies. Walter et al. (1972) recognized the bacterial origin of ► [stromatolites](#) composed of nearly amorphous silica. He also considered that hot springs were a good depositional analogue for ► [banded iron formations](#). Geobiological studies at Yellowstone have resulted in the discovery and identification of extremely acidic (pH = 1) ► [endolithic](#) microbial communities inhabiting the pore space of rocks in geothermal deposits. Subjected to silica mineralization, such endolithic communities constitute ► [biomarkers](#) that might potentially be preserved in the geological record and could provide

important clues about ancient life associated with ► [hydrothermal environments](#) on the Earth or elsewhere in the Solar System (Walker et al. 2005). Mineral deposits associated with the hot springs have also been used for testing remote sensing instrumentation (infrared and visible spectroscopy) for future exploration of extinct mineralized hydrothermal deposits on ► [Mars](#) (Helmann and Ramsey 2004).

The discovery of a heat-resistant bacteria at Yellowstone led to the discovery of the polymerase chain reaction (PCR, or DNA amplification) by Kary B. Mullis in 1983 (e.g., Saiki et al., 1988), a finding that earned him the 1993 Nobel Prize in Chemistry.

Yinghuo-1, a Chinese satellite to explore ► [Mars](#), was part of the ► [Phobos-Grunt](#) mission which was lost few days after the launch (November 9, 2011). The probe, almost a cube ($71 \times 75 \times 60$ cm) weighing 110 kg, was dedicated to study the Martian atmosphere. The five-instrument payload included a plasma package, a magnetometer, a radio-occultation sounder, and an optical imaging camera with 200 m resolution at the lowest altitude.

YY Orionis Star

Steven W. Stahler
Department of Astronomy, University of
California, Berkeley, CA, USA

Keywords

Young star · Stellar wind

Definition

One of the characteristics of ► [T Tauri stars](#) is the generation of powerful winds. These winds are found spectroscopically, through the presence of a blue-shifted absorption dip in an optically thick emission line. Such lines are said to have P Cygni profiles. In YY Orionis stars, some lines have inverse P Cygni profiles. That is, the dip occurs in the red part of the spectrum, a signature that relatively cool gas is falling toward the star. From the types of lines in which the two different profiles appear, it seems that material close to the star is falling onto it while gas farther out is moving in a wind. A large fraction of classical T Tauri stars exhibit this complex behavior.

Z

Z (Astrophysics)

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

In astrophysics, Z is used to denote the mass fraction of all elements except hydrogen and helium in a star or other astronomical object. Those elements, considered as “heavy elements” and often called “metals” by astronomers, differ with respect to hydrogen and helium because their production implies processing by a star, either through nuclear reactions during the Main Sequence or giant phase or as a consequence of a ► [supernova](#) explosive event at the end of the star’s life. The abundance of these heavy elements is thus a very important indicator of the processing by stars in a galaxy.

In contrast, lower case z is used by astronomers to denote the ► [redshift](#) of a (typically) distant object moving away from the observer.

Zero Age Main Sequence

Nikos Prantzos
Institut d'Astrophysique de Paris, Paris, France

Definition

The zero age main sequence (ZAMS) is defined by the positions occupied in the Hertzsprung-Russell diagram (luminosity versus effective temperature) by stars that are igniting for the first time their hydrogen fuel. Since the stellar luminosity increases with time during hydrogen fusion, the ZAMS locus for a star of given mass is its lowest position on the main sequence (for a given metallicity and rotational velocity). On the ZAMS, i.e., 4.5 Gyr ago, the Sun was 30% less luminous than today.

Zinc Isotopes

Terry T. Isson^{1,2}, Mingyu Zhao¹ and Noah J. Planavsky¹

¹Department of Geology and Geophysics, Yale University, New Haven, CT, USA

²University of Waikato, Tauranga, New Zealand

Definition

Zinc has five naturally occurring stable isotopes (⁶⁴Zn, ⁶⁶Zn, ⁶⁷Zn, ⁶⁸Zn, and ⁷⁰Zn) with natural abundances of 48.6%, 27.9%, 4.1%, 18.8%, 0.6%, respectively. Because ⁶⁴Zn and ⁶⁶Zn are the most abundant, variations to the ratio of ⁶⁶Zn/⁶⁴Zn are typically reported, expressed in the conventional delta notation ($\delta^{66}\text{Zn}$) relative to the JMC-Lyon (close to exhaustion) and AA-ETH (latest) Zn standards.

Zinc isotopes are routinely measured by multi-collector inductively coupled plasma source mass spectrometry (MC-ICP-MS). Measurements by the thermal ionization mass spectrometry (TIMS) are also possible but difficult due to the element's high first ionization potential, leading to a low Saha constant. Common column protocols for Zn purification can easily achieve sufficient recovery rate, but the degree of purification should be high for Zn as many elements can generate an interference on Zn isotopic measurements. Mass bias during Zn isotopic measurement can be corrected using techniques such as direct standard sample bracketing, Cu doping, and double spike. The measurement of Zn isotopes on natural samples, though relatively new, has already demonstrated utility in a wide variety of fields including ecology, environmental studies, geology, oceanography, planetary science, and medicine. This entry summarizes some notable applications of Zn isotopic work to astrobiology and the study of Earth's evolution. While mass independent fractionations of Zn isotopes have been predicted to occur with redox reactions between Zn^0 and Zn^{2+} , these have yet to be clearly

demonstrated in natural samples. Therefore, only mass-dependent applications are explored here.

The global cycling of Zn and its isotopic expressions at Earth's surface (e.g., within soils and in seawater) have been found to be dominated to a large degree by biological processes (Fig. 1). This is perhaps unsurprising given that Zn is a key nutrient for all life on Earth. Zn is the second most abundant micronutrient in phytoplankton biomass (Twining and Baines 2013) and is required as a cofactor in the functioning (activity) of over 300 enzymes in all six classes of enzymes, including key enzymes such as carbonic anhydrase and alkali phosphatase. It is well established that Zn plays a fundamental role in the replication and transcription of DNA, gene expression, and intra- and intercellular signaling (Maret 2013). Zinc is, therefore, essential for the growth and development of all known types of life. Culture experiment has demonstrated that Zn can be either toxic or limiting depending on Zn concentration, speciation, and the species of algae or bacteria. Nutrient limitation is never simple, not only because of co-limitation (e.g., Shaked et al. 2006) but also because other trace metals such as Cd and Co can substitute at least some of the functions of Zn (e.g., Price and Morel 1990; Sunda and Huntsman 1995).

Eukaryotes, in particular, have a strong affinity for Zn, relative to unicellular prokaryotes. In fact, based on predicted Zn-binding proteins derived from whole genome sequences, all major eukaryotic clades have been observed to bear high Zn requirements (Dupont et al. 2010; Isson et al. 2018). This is consistent with the most natural measurements of modern eukaryotic phytoplankton which appear to have elevated Zn demands and elevated Zn/C ratios relative to cyanobacteria (Twining et al. 2011). This contrast in Zn usage has been linked to the abundance of proteins (e.g., Zn fingers and RING domains) localized within the nucleus in eukaryotes, which are responsible for DNA–RNA transcription and protein–protein interactions (Dupont et al. 2010).

The distribution of Zn in seawater exhibits a simple nutrient-type profile, indicating that

Zinc Isotopes, Fig. 1 Range of $\delta^{66}\text{Zn}$ values of naturally occurring samples (Top). Planetary samples (green). $\delta^{66}\text{Zn}$ values of sources into and sinks out of the modern oceanic

reservoir (blue and yellow, respectively), fluxes (in %) are represented in the cartoon cross section of Earth's surface environment (bottom)

biological processes play a role in regulating the marine Zn cycle. Recent works that have attempted to reconcile Zn and Zn isotope vertical profiles reveal that in addition to biological uptake, reversible scavenging plays a role in driving Zn export from the surface oceans (Weber et al. 2018). While culture work indicates that the biological assimilation of Zn can be associated with variable δ isotopic fractionation values from the dissolved pool (John et al. 2007), the bulk of organic matter being exported from the marine environment is isotopically lighter than the global seawater average (Isson et al. 2018). This is responsible for sustaining a total dissolved marine isotopic signature that is heavier than that of riverine inputs (Fig. 1). On this basis, Zn isotopes have emerged as a potential tracer for organic matter sequestration and have recently been adopted to reconstruct changes in primary productivity and marine eukaryotic productivity over the course of Earth's history (Isson et al. 2018). In particular, Zn isotopes provide evidence for a late (post 800 Ma) rise of a productive, eukaryote-rich ecosystems (Isson et al. 2018) that are consistent with the emerging view from biomarker work (Brocks 2018).

There have been several other notable applications of Zn isotopes. Zn is a highly volatile element under solar nebular conditions and exhibits strong isotopic fractionation during volatilization. While the Zn isotopic composition of terrestrial and Martian rocks is indistinguishable (Fig. 1), lunar mare basalts span a much larger range. This has been suggested to be indicative of the style of the formation of the moon (Paniello et al. 2012). In medicine, Zn isotopes are currently being developed as a potential biomarker of breast cancer, on the basis that there is a difference in the Zn concentration of breast tissue between its healthy and malignant states and that this process is associated with the preferential enrichment of the tissue in the lighter isotope (Larner et al. 2015). Over the next decade, the use of Zn isotopes can be expected to increase substantially.

Zircon

Ian S. Williams
Research School of Earth Sciences, ANU College of Science, The Australian National University, Canberra, ACT, Australia

Keywords

Jack Hills · Hadean · Geochronology · U-Th-Pb isotopes · Oxygen isotopes · Moon · Meteorites

Synonyms

Zirconium silicate

Definition

Zircon is a silicate mineral (zirconium silicate) with the chemical formula ZrSiO_4 (tetragonal crystal system). It is a dense (4.7 g/cm^3), hard (7.5), pale pink to reddish brown, usually fine-grained ($<1 \text{ mm}$) trace mineral common in sedimentary and in silica-saturated (felsic) igneous rocks.

Overview

Zircon occurs in trace amounts in a wide variety of quartz-bearing ► [igneous rocks](#). It is physically and chemically robust under a wide range of geological pressures and temperatures, so it is also common in ► [metamorphic rocks](#) and as a detrital mineral in sediments and sedimentary rocks. Zircon occurs in lunar rocks and regolith and in some classes of meteorites (e.g., chondrites, eucrites, mesosiderites, lunaites).

Crystallizing zircon incorporates a variety of trace elements, including Hf, the Rare Earth Elements (REE), U, and Th. Because it incorporates little Pb and has a high closure temperature for trace element diffusion, zircon is widely used for ► [geochronology](#) using the radioactive decay of U and Th to Pb. U-rich zircon is prone to accumulate radiation damage, becoming metamict

(*metamict* – having a disrupted crystal structure due to accumulated radiation damage), but above about 300°C , the crystal structure anneals.

Zircon grains are commonly zoned, preserving a record of the changing conditions under which they crystallized as chemical and isotopic differences on the scale of a few microns. Zircon can survive the partial melting of its host rock. It is not unusual for zircon grains from igneous or metamorphic rocks with a complex history to consist of a core of protolith zircon surrounded by successive overgrowths of zircon crystallized or recrystallized during later thermal events. The age and nature of those events can be determined by chemical and isotopic microanalyses of U-Th-Pb, O, Hf, and the REE.

The oldest dated terrestrial material is Hadean detrital zircon (Fig. 1) from the Jack Hills, Western Australia (4.4–4.2 Ga). Quartz inclusions in, and the oxygen isotopic compositions of, these zircon grains have been interpreted as evidence for continental crust and oceans on Earth within about 150 Myr of planetary formation (Wilde et al. 2001).

Zircon from lunar rocks and soils provides a direct means of dating the early lunar crust, showing that the lunar magma ocean cooled sufficiently for differentiated rocks to crystallize within 200 Myr of the formation of the Moon and that they continued to be produced for at least 400 Myr thereafter (Meyer et al. 1996). Some eucrites contain zircon of the same age as the Solar System, from which the initial Hf isotopic composition of the Solar System has been determined (Iizuka et al. 2015).

Asteroidal dust · Cometary dust · Circumstellar disks · Exo-zodiacal clouds · Gegenschein · IDPs · Meteors · Zodiacal cloud

Definition

The zodiacal light is a faint veil of light visible in the Earth's night sky. Brighter towards the Sun and the ► [ecliptic](#), it originates in solar light scattered by a huge cloud of dust particles, mostly of cometary and asteroidal origin. The brightness increases toward the Sun and the near-ecliptic region; it corresponds to an increase in the space density of the cloud, which has a lenticular shape around the Sun. A minor brightness enhancement toward the antisolar region corresponds to a backscattering effect. Thermal emission from zodiacal particles forms, away from the galactic plane, the most prominent component in the near-infrared sky.

History

Although some hints are suspected in ancient texts, Childrey (1661) possibly gave the first description of the zodiacal light. Cassini (1683) provided a detailed interpretation, with the zodiacal light originating in a flattened cloud that scatters better the light when the line of sight gets closer to the Sun and its equator. Dortous de Mairan (1733) suggested that the cloud expands further than the terrestrial orbit. During the nineteenth century, Brorsen (1854) described a slight brightness enhancement around the antisolar direction, later called *gegenschein* by Humboldt, and Wright (1874) provided evidence for the linear polarization of the zodiacal light.

Precise measurements of the brightness and polarization of the zodiacal light have begun in the twentieth century. The question of the stability of the zodiacal cloud on a scale of more than a few centuries or millennia is thus still open, together with that of the characteristics of exozodiacal clouds.

Overview

The zodiacal light, seldom visible through the naked eye as a faint cone of light (Fig. 1), extends over the whole celestial sphere; it represents a

Zodiacal Light,

Fig. 1 Zodiacal light over La Silla. The image was taken in September 2009 at ESO's Observatory in Chile (2400 m, 29° S), facing west after sunset. (From Y. Beletsky)

foreground veil for the observation of faint, possibly extended, astronomical sources. The characteristics of the zodiacal light and of the zodiacal thermal emission allow the retrieval of some of the intrinsic properties of the zodiacal dust, which has recently been found to be, within the inner solar system, mainly built of cometary dust, and thus rich in organic compounds.

Basic Methodology

Introduction

In the absence of contamination by terrestrial lights and moonlight, the zodiacal light appears to the naked eye as a faint whitish cone of light, about 1 h after sunset or before sunrise. It is visible when the zodiac (that is, the ring of constellations along the ecliptic) is high above the horizon. It is thus relatively easy to detect in tropical latitudes, while, in midlatitudes, it is mainly detectable in spring toward the west after the evening twilight and in autumn toward the east before the morning twilight (Fig. 2). Spectrographic observations have established that the zodiacal light spectrum is similar to that of the Sun. Together with measurements of the partial linear polarization, expected from solar light scattered by an optically thin medium, such results have confirmed that the zodiacal light originates in the scattering of light by the zodiacal cloud. This interplanetary cloud is formed by tiny dust particles (in the tens of micron-sized range)

and mostly extends from the Sun to the asteroidal belt. Forward scattering makes it rather bright when observing at small solar angles, while back-scattering builds up the gegenschein.

Although the zodiacal light is entangled with other components of the light of the night sky, precise ground-based measurements, together with circum-terrestrial and interplanetary space observations (from, e.g., OSO 2 and 5, D₂A, Skylab, Helios 1 and 2, Pioneer 10 and 11, SMEI or New Horizons spacecraft), have pointed out spatial and annual variations, respectively, attributed to the crossing of near-Earth meteoritic streams (Levasseur and Blamont 1973) and to the localization of the plane of symmetry of the cloud; at 1 au from the Sun, it is close to the invariable plane of the solar system, with an ascending node about 96° and an inclination about 1.5° (Dumont and Levasseur-Regourd 1978). After corrections are made, tables and maps providing information on the average zodiacal light brightness and linear polarization, as a function of the ecliptic latitude and the helio-ecliptic longitude of the observations, are derived (Leinert et al. 1998; Buffington et al. 2016; Lasue et al. 2020). Toward the ecliptic poles (where the zodiacal light is minimal), the zodiacal brightness is about $76 \times 10^{-8} \text{ W m}^{-2} \text{ sr}^{-1} \mu\text{m}^{-1}$ for a wavelength of about 0.55 μm , and its partial linear polarization is about 20%. Studies in the infrared domain (from, e.g., IRAS, COBE, or Spitzer spacecraft, Fig. 3) have established that this thermal emission

Zodiacal Light,

Zodiacal Light, Fig. 3 Image of the infrared sky at 25, 60, and 100 μm (represented, respectively, in *blue*, *green*, and *red* colors) obtained from the NASA COBE spacecraft. The Milky Way lies horizontally across the

middle of the image; the zodiacal thermal emission is also a prominent feature by 25 μm (here in *blue*) in the vicinity of the ecliptic plane

is a most prominent component in the 5–100 μm spectral domain. Infrared surveys accentuate the spatial variations that typically originate in low-ecliptic latitude dust bands attributed to collisions between [▶ asteroids](#), and in dust trails along the perihelion part of the orbits of several short-period [▶ comets](#) (Fig. 4).

Dust Properties, Orbits, and Sources

The brightness and thermal emission vary along the observational line-of-sight. Inversion techniques are thus needed to tentatively derive local values of brightness and polarization, as well as estimations (through numerical and experimental simulations) of the properties of the dust particles,

Zodiacal Light,

Fig. 4 Dust trail of comet 67P/Churyumov-Gerasimenko. The trail was detected from the NASA Spitzer Space Telescope at 24 μm . (From W. Reach et al.)

(e.g., shape, geometric albedo, spatial density, temperature). Such approaches have typically established that the tiny dust particles are not spherical and may consist of dark aggregates with various porosities. The size distribution of the dust particles (as deduced from near-Earth cumulative fluxes measurements) follows approximately a power law with an index of -3 for particles below 20 μm , with a value of about -4.4 for larger sizes. For solar distances of about 1 AU in the ecliptic, the dust particles consist of a roughly equally divided mixture of minerals, such as silicates, and more absorbing organic molecules, such as HCN polymers and various tholins (e.g., Lasue et al. 2007, 2020). The zodiacal cloud is heterogeneous: near the ecliptic plane at 90° phase angle; the local albedo increases with decreasing solar distance R as about $R^{-0.3}$, while the local polarization decreases with decreasing R and presents a steep decrease below 0.3 au (Dumont and Levasseur-Regourd 1988; Levasseur-Regourd et al. 1991).

Such results are in agreement with the dynamical properties of the particles that build up the zodiacal cloud (Dermott et al. 2001; Koschny et al. 2019). Their orbits are not stable, since they are not only subject to the solar gravity, but also to radiative forces, such as the ► [Poynting-Robertson drag](#) that causes their orbits to spiral towards the Sun and the solar radiation pressure that expels the smallest and fluffiest particles (for sizes below $\approx 1 \mu\text{m}$) out of the solar system. Meanwhile, dust particles may suffer weathering, collisions, radiative torques, or sublimation of their (semi-volatile) organics, and thus fragmentations, leading to the abovementioned drastic decrease in polarization close to the Sun.

Therefore, assuming that the zodiacal cloud is (or at least has been for a while) stable, continuous sources of new particles are required.

The question of the origin of dust particles that replenish the zodiacal cloud has been extensively discussed. After the detection of asteroidal bands and cometary trails by IRAS in 1983, it had been suggested that the main source could be dust released by asteroidal collisions (Sykes and Greenberg 1986), while evidence was found for dust particles trapped in a circumsolar ring in resonant lock with the Earth (Reach 2010). Other minor sources of dust have been detected, such as dust from Mars, from the Jupiter and Saturn systems or interstellar dust (e.g., Rowan-Robinson and May 2013; Jorgensen et al. 2020). However, the main source, at least in the inner solar system, presently seems to come from periodic comets (Nesvorný et al. 2010; Plane 2012). Such dust particles are estimated to contribute for at least 80% in mass to the flux of micrometeorites reaching the Earth upper atmosphere and to plunge into it at relative velocities below 15 km/s (Carillo-Sanchez et al. 2016; Nesvorný et al. 2020). The properties of interplanetary dust particles collected in the atmosphere (CP-IDPs) or in Antarctica snows (UCAMMs) indeed fairly agree with those of cometary dust particles derived from missions to periodic comets, such as ► [Vega](#), ► [Giotto](#), ► [Stardust](#), and all the more ► [Rosetta](#). While such particles have low densities (few tens to hundreds of kg/m^3), are aggregates of grains (down to sizes $\approx 100 \text{ nm}$) with hierarchical structures, and are rich in carbonaceous compounds, it is indeed estimated that irregularly shaped particles and fluffy aggregates bring up to $\sim \pi^3$ times more organics to the Earth's

surface in volume than compact spherical particles (e.g., Mannel et al. 2016; Bardyn et al. 2017; Levasseur-Regourd et al. 2018).

Astrobiological Implications, Back in Time and Away in Space

There is evidence for a major contribution of cometary dust to the zodiacal cloud and to the flux of cosmic dust particles reaching the surface of the Earth (Flynn et al. 2004). During the ► [Late Heavy Bombardment](#), which possibly took place about 4 million years ago, large amounts of cometary dust could be released by cometary nuclei injected in the inner solar system. The spatial density of the zodiacal cloud was orders of magnitude greater and the zodiacal light was at least 10^4 times brighter than nowadays (Nesvorný et al. 2010). The fluffy structure and moderate velocity of dust particles of cometary origin would have favored the survival of their organic compounds during their atmospheric entry (Levasseur-Regourd et al. 2006, 2018). Such dust particles, mostly coming periodic comets, are also a major source of cosmic dust in the atmospheres of terrestrial planets, and even possibly of giant planets (Plane et al. 2018; Carillo-Sanchez et al. 2020). They could possibly have significantly contributed to the enrichment of early Earth and telluric planets in carbonaceous compounds.

Far away from our solar system, circumstellar disks (such as protoplanetary and debris disks) and exozodiacal dust clouds have been discussed as a potential source of noise in the detection of exoplanets, and specifically of exo-Earths inside the star's habitable zone. While modeling of dust in such disks seems to favor the presence of irregular porous particles, instead of compact spherical particles (Levasseur-Regourd et al. 2020), a good understanding of the properties of our zodiacal cloud is mandatory to define relevant models of exo-zodiacal clouds. While a significant part of their dust may, as well as in our solar system, originate in small bodies, many questions about the contribution of dust streams from ► [hot Jupiters](#) and the geometries of planetary systems with highly eccentric planets would need to be carefully considered.

Key Research Findings

Source of the Zodiacal Light

The zodiacal light originates in the scattering of solar light by a wide cloud of dust particles, which somehow extends from the Sun to the asteroidal belt along the ecliptic plane. Numerous observations, together with numerical and experimental simulations, have established that these dust particles are irregular, porous, and rich in organic matter.

Origin of Zodiacal Dust Particles

The main source of zodiacal dust particles seems to be, in the inner solar system, dust released by periodic comets. Theoretical and observational approaches have established that dust particles from periodic comets contribute for at least 80% in mass to the flux of micrometeorites reaching the Earth upper atmosphere.

Astrobiological Significance

There is evidence for a major contribution of cometary dust to the zodiacal cloud and to the flux of cosmic dust particles reaching the surface of the Earth. During a ► [Late Heavy Bombardment](#), fluffy zodiacal dust particles entering the atmosphere of terrestrial planets at rather low speeds could have released huge amounts of organic matter on their surfaces.

Future Directions

Studies of zodiacal light and interplanetary dust had flourished at the beginning of the space age with concerns about the risks of impacts on spacecraft, fortunately found to be limited by the low spatial density of the zodiacal dust. Key questions are presently related to differences between periodic and dynamically new comets, and to the delivery of organics to planets and exoplanets, nowadays and in the early solar system, not to mention interstellar comets and exo-zodiacal dust.

Future space missions are expected to provide answers to the abovementioned questions. Comet Interceptor mission (an ESA-JAXA project) could reveal crucial differences between the properties

of dust within periodic comets and dynamically new comets. An interstellar probe, as presently studied in the USA, could perform in situ studies of zodiacal dust and of interstellar dust in the local galactic environment. Meanwhile, new measurements of zodiacal and exozodiacal light, together with more elaborate numerical and experimental simulations (on Earth and under long duration microgravity environment) are being developed.

Washington, DC, USA

Center for Chemical Evolution, Georgia Institute
of Technology, Atlanta, GA, USA

Definition

In chemistry, a zwitterion (from the German “hybrid ion”), or inner salt, is a compound containing both a formal positive and a formal negative charge on different atoms. As the molecule contains two opposite charges, it is electrically neutral. Some common examples of zwitterions are ► [amino acids](#) such as ► [glycine](#) (at physiological pH, as the state of the ionizable groups is pH dependent), although many amino acids contain a third ionizable group. Most zwitterions are fairly soluble in water and thus poorly soluble in many organic solvents.

Cross-References

- [Amino Acid](#)
- [Glycine](#)

All species were detected by radio astronomy except molecules marked with one or two *asterisks* that were only detected in the infrared domain by means of their rovibrational or rovibronic spectra, respectively. Entries with a *question mark* are tentative – some are presented as detections in the literature. Entries with a *question mark* in parentheses are likely detections, viewed as somewhat tentative because of the small number of (unambiguous) lines – some are presented as detections in the literature. In some instances, detections are viewed as secure in spite of a small number of lines; available documentation gives further details. The *l* indicates a linear molecule or a molecule that contains a linear backbone; the *c* indicates a cyclic molecule or a molecule with a cyclic subunit. The questionable detections of aminoacetic acid, H₂NCH₂COOH, aka glycine, and 1,3-dihydroxypropanone, aka dihydroxyacetone, do not appear in the table.

General Information

Whole Earth	
Age of the Earth	4.550 Ga
Age of the oldest known terrestrial material (zircon from Jack Hills, Australia)	4.404 Ga
Age of the oldest known terrestrial rock (Acasta gneiss, Canada)	4.030 Ga
Equatorial radius	6378.136 km
Polar radius	6356.753 km
Ellipticity	0.00335281
Total surface area	$510 \times 10^6 \text{ km}^2$
Ocean surface area	$361 \times 10^6 \text{ km}^2$
Continental surface area	$149 \times 10^6 \text{ km}^2$
Mass	$5.974 2 \times 10^{24} \text{ kg}$
Mean density	5.515 g cm^{-3}
Deepest oceanic trench (Marianas)	11,034 m
Highest mountain (Everest)	8848.86 m
Present-day oceanic ridge length	~80,000 km
Solid inner core	
Depth from surface	5155 km
Radius	~1223 km
Average density	12 g cm^{-3}
Volume	$8.45 \times 10^{10} \text{ km}^3$
Mass	$1.18 \times 10^{23} \text{ kg}$
Liquid outer core	
Depth	2891 km
Thickness	~2264 km
Average density	10 g cm^{-3}
Volume	$1.65 \times 10^{11} \text{ km}^3$
Mass	$1.65 \times 10^{24} \text{ kg}$
Lower mantle (mesosphere)	
Depth	670 km
Thickness	~2231 km
Average density	5 g cm^{-3}

(continued)

Volume	$5.87 \times 10^{11} \text{ km}^3$
Mass	$2.93 \times 10^{24} \text{ kg}$
Upper mantle	
Depth	~30 km
Thickness	~640 km
Average density	3.2 g cm^{-3}
Volume	$3.08 \times 10^{11} \text{ km}^3$
Mass	$0.986 \times 10^{24} \text{ kg}$
Oceanic crust	
Average thickness	7 km
Average density	2.9 g cm^{-3}
Age of the oldest known oceanic crust	0.165 Ga
Volume	$2.0 \times 10^9 \text{ km}^3$
Mass	$6.2 \times 10^{21} \text{ kg}$
Continental crust	
Average thickness	30 km
Average density	2.75 g cm^{-3}
Age of the oldest known continental crust	4.03 Ga
Volume	$7 \times 10^9 \text{ km}^3$
Mass	$1.9 \times 10^{22} \text{ kg}$
Average surface magnetic flux density	$5 \times 10^{-5} \text{ T}$
Heat flux	$42 \times 10^{12} \text{ W}$
Range of lithospheric plate motion rate	$1\text{--}10 \text{ cm year}^{-1}$

Decay Constants (λ)

Mineralogical Short Summary

Silicates

More than 95% of the Earth’s crust and mantle rock minerals are silicates. Silicates dominate also the other telluric planets of our Solar system and most likely the Earth-like rocky exoplanets. Silicate structure is based on the tetrahedron $[\text{SiO}_4]^{4-}$; however, sometimes one of the silicon (Si^{4+}) atoms is replaced by an atom of aluminum (Al^{3+}) which has an ionic radius close to that of silicon, but a different valency number. The different families of silicate minerals consist of different spatial arrangements of silica tetrahedra. The tetrahedron $[\text{SiO}_4]^{4-}$ is not electrically neutral; thus, it must be linked with different cations to reach electric neutrality.

Basic framework of silicates: oxygen atoms (green) are located at the extremities of a tetrahedron. The silicon atom (red) occupies the center of the silica tetrahedron. On the right projection, the oxygen atom located above the tetrahedron is represented by dots, and the atom sizes are reduced half their real size to make the structure visible.

Tectosilicates: these anhydrous minerals consist in a 3D framework of silicate tetrahedra. This is the largest mineral group on Earth, comprising nearly 75% of the crust. The series of plagioclases are common minerals in the Moon’s highlands (anorthosite rocks).		
Family of silica		
Quartz	SiO_2	
Coesite	SiO_2	At pressure >2 GPa
Feldspar		
Potassic feldspar	Orthoclase	$K [\text{AlSi}_3\text{O}_8]$
Plagioclase: <i>plagioclase is a solid-solution series having a composition intermediate between albite and anorthite end-members. Alkaline feldspars range from albite to orthose.</i>		
Sodic feldspar	Albite	$\text{Na} [\text{AlSi}_3\text{O}_8]$
Calcic feldspar	Anorthite	$\text{Ca} [\text{Al}_2\text{Si}_2\text{O}_8]$
Feldspathoid		
Leucite	$K [\text{AlSi}_2\text{O}_6]$	
Nepheline	$\text{Na} [\text{AlSiO}_4]$	

3D structure of tectosilicates sharing four oxygen atoms

(continued)

Phyllosilicates: Hydrated minerals where tetrahedra share three oxygen atoms resulting in a planar framework. Clay minerals belong to this family.

Talc	$Mg_3 [Si_4O_{10}] (OH)_2$
------	----------------------------

Micas

Muscovite (white mica)	$KAl_2 [AlSi_3O_{10}] (OH)_2$
---------------------------	-------------------------------

Biotite (brown mica)	$K(Fe, mg)_3 [AlSi_3O_{10}] (OH)_2$
----------------------	-------------------------------------

Chlorites

Clinocllore	$Mg_5 Al (OH)_6 [AlSi_3O_{10}] (OH)_2$
-------------	--

Serpentines

Antigorite	$Mg_6 (OH)_6 [Si_4O_{10}] (OH)_2$
------------	-----------------------------------

Clay

Kaolinite	$Al_4 (OH)_6 [Si_4O_{10}] (OH)_2$
-----------	-----------------------------------

Illite	$KAl_2 [AlSi_3O_{10}] (OH)_2$
--------	-------------------------------

Inosilicates: Tetrahedra share only two oxygen atoms resulting in a linear framework. They are commonly called “chain silicates.” common minerals in mafic and intermediate magmatic rocks, some of them are found in meteorites (such as enstatite in the enstatite chondrite family).

Single-chain inosilicates: Pyroxenes (*anhydrous minerals*)

Orthopyroxenes

Enstatite	Mg_2	$[Si_2O_6]$
-----------	--------	-------------

Hypersthene	$(Fe, Mg)_2$	$[Si_2O_6]$
-------------	--------------	-------------

Clinopyroxenes

Diopside	$CaMg$	$[Si_2O_6]$
----------	--------	-------------

Augite	(Ca, Fe, Mg) (Fe, Mg)	$[Si_2O_6]$
--------	------------------------------	-------------

Jadeite	$NaAl$	$[Si_2O_6]$
---------	--------	-------------

Aegyrine	$NaFe^{+++}$	$[Si_2O_6]$
----------	--------------	-------------

Double-chain inosilicates: Amphiboles (*hydrated minerals*)

Ortho-amphiboles

Anthophyllite	Mg_7	$[Si_8O_{22}] (OH, F)_2$
---------------	--------	--------------------------

Clino-amphiboles

Cummingtonite	$(Mg, Fe)_7$	$[Si_8O_{22}] (OH, F)_2$
---------------	--------------	--------------------------

Actinolite	$Ca_2 (Fe, Mg)_5$	$[Si_8O_{22}] (OH, F)_2$
------------	-------------------	--------------------------

Hornblende	$(Ca, Na, K)_2$ $(Fe, MgAl)_5$	$[Si_6 (Si, Al)_2 O_{22}]$ $(OH, F)_2$

------------	---------------------------	--------------------------

Planar structure of phyllosilicates formed by parallel sheets of silicate tetrahedra

Single chain of silica tetrahedra of pyroxenes

Double chain of silica tetrahedra

(continued)

Sorosilicates: Hydrated minerals sharing only one oxygen atom resulting in isolated double tetrahedra groups		
Lawsonite	$CaAl_2$	$[Si_2O_7](OH)_2, H_2O$

Epidotes		
Zoisite	Ca_2Al_3	$[(Si_2O_7)(SiO_4)O](OH)$
Allanite	$(Ca, La, Ce)_2(Al, Fe^{+++})_3$	$[(Si_2O_7)(SiO_4)O](OH)$

Nesosilicates: Anhydrous minerals resulting in single silica tetrahedra. Olivine is a common mineral in terrestrial mantle rocks (peridotite), while zircon is a common accessory mineral in felsic magmatic rocks. Garnets form a common mineral group in metamorphic rocks as well as in high-pressure peridotites.

Peridots		
Forsterite	Mg_2	$[SiO_4]$
Fayalite	Fe_2	$[SiO_4]$
Olivine*	$(Mg, Fe)_2$	$[SiO_4]$

*The olivine group is a solid-solution series ranging from the iron end-member fayalite and the magnesium end-member forsterite.

Garnet		
Pyrope	Mg_3Al_2	$[SiO_4]_3$
Almandine	Fe_3Al_2	$[SiO_4]_3$
Grossular	Ca_3Al_2	$[SiO_4]_3$

Zircons		
Zircon	Zr	$[SiO_4]$
Thorite	Th	$[SiO_4]$

Sub-nesosilicates: Like nesosilicates, sub-nesosilicates consist of single silica tetrahedron; however, in addition, they possess oxygen atoms that are not linked to Si or Al in tetrahedron

Andalusite	Al_2O	$[SiO_4]$	Low P and low T
Kyanite	Al_2O	$[SiO_4]$	Moderate P, low T
Sillimanite	Al_2O	$[SiO_4]$	High T
Staurolite	$Fe(OH)_2$	$([SiO_4])_2$	
Chloritoid	$(Fe, Mg)Al_2O$	$[SiO_4](OH)_2$	
Sphene (titanite)	$CaTiO$	$[SiO_4]$	

Sorosilicate framework with the sharing of a single oxygen atom

Nesosilicate framework with single tetrahedral

Nonsilicate Minerals

By this term are designated all mineral groups that do not contain silicon. They appear in all kinds of rocks, but some of them mainly occur on the surface of the Earth as sedimentary rocks (carbonates, halides, hydroxides, sulfates, etc.) or in ore deposits. Some of them are commonly found in meteorites (such as spinel, a common mineral in the Ca-Al-rich inclusions (CAIs)) or on other planetary surfaces (iron oxides, hydroxides, and halides in Mars)

Rock Classification for Astrobiologists

Three main rock types exist on Earth and on some telluric (or rocky) planet and moon:

1. Endogenous or magmatic (synonym: igneous) rocks resulting from crystallization of magma. Typically, magma is generated at depth in the crust (anatexis) or in the mantle.
2. Exogenous or sedimentary rocks resulting from alteration, erosion, transport, deposition, and ► [diagenesis](#) of rock debris (clastic or detrital rocks) or direct precipitation of dissolved salts from a fluid (evaporites). They are generated and emplaced at the surface of a planet.
3. Metamorphic rocks resulting from mineralogical and structural changes of preexisting sedimentary or magmatic rocks when subjected to heat and pressure changes in the interior of the planet.

Magmatic or Igneous Rocks

Igneous rocks result from magma crystallization such that their classification is mainly based on two parameters: (1) the place (and conditions) where magma crystallized and (2) the chemistry of the crystallizing magma.

Place of Magma Crystallization

Depending on their temperature, density, and viscosity, some magmas cool and solidify at depth, within the outer rocky layer of a planet, i.e., the crust. In other words, they do not reach the planetary surface. These accumulations of solidified magmas at depth are termed “plutons” or “batholiths” and the derived rocks “plutonic rocks.” If magmas can reach the surface of a planet, they are termed “effusive” and derived rocks “volcanic rocks.” Usually volcanic rocks, as the term indicates, are emitted at the surface through fractures or centers, progressively building constructional volcanic edifices or “volcanoes.” Textures of igneous rocks are basically controlled by the rate of magma cooling. If magmas cool very slowly, as in plutons, igneous rocks develop large conspicuous crystals, this coarse-grained texture being called “granular.” Occasionally some crystals (phenocrysts) are larger than the groundmass, in which case the texture is known as porphyritic. If the magmas cool rapidly, as in volcanic effusive rocks, the crystals are smaller and elongated (microlites), such that the texture is referred to as “microplitic.” In the case of brutal cooling, crystals do not have enough time to form, resulting in a glass (not crystallized matter commonly called “groundmass”), and then the texture is called “hyaline” or “glassy.”

Chemistry of the Crystallizing Magma

The chemical composition of magmas controls the type of minerals that will be crystallized. Schematically, magmas and derived igneous rocks are classified based on the SiO_2 and MgO content. The MgO -rich ($\sim 30\%$) and SiO_2 -poor ($\sim 42\%$) magmas are termed “ultramafic.” The MgO -poor ($\leq 1\%$) and SiO_2 -rich ($\geq 70\%$) magmas are termed “felsic.” Between these two endmembers, igneous rocks are referred to as mafic and intermediate. Crystallization processes and the chemical composition of magmas account for the diversity of existing igneous rocks (Table 1).

The abovementioned classification is very rough. Geologists propose more elaborated classification schemes based mainly on the nature of minerals contained in rocks (Fig. 1). For example, granite is a plutonic endogenous igneous rock rich in silica (quartz) and feldspars (plagioclase albite [$\text{NaAlSi}_3\text{O}_8$] or anorthite [$\text{CaAl}_2\text{Si}_2\text{O}_8$] and alkaline feldspar orthoclase [KAlSi_3O_8]). Depending on the type of feldspars contained in granite, we can distinguish the following parental rocks:

- *Tonalite*: dominated by calcic plagioclase
- *Trondhjemite*: dominated by sodic plagioclase
- *Granodiorite*: containing two feldspars but with plagioclase more abundant than the potassic feldspar
- *Granite*: containing two feldspars but with potassic feldspar equal or more abundant than plagioclase

Sedimentary Rocks

Sedimentary rocks are formed on the surface of a planet by chemical ► [weathering](#) and mechanical erosion of preexisting rocks of any nature, igneous, metamorphic, or sedimentary. The detritus is transported as solid particles in suspension by rivers, glaciers, or wind while ions are transported in solution in water. Transport is achieved in sedimentary basins such as lakes, epicontinental seas, or the ocean where they form deposits of sediments (such as sand). By progressive burial by other sediments and

Geological Data, Table 1 Simplified igneous rock classification based on the crystallization processes (controlling the size and form of the crystals) and the chemical composition of magmas which controls the relative abundance and nature of the minerals (Photos H. Martin)

	Plutonic Rocks Magma crystallized at depth	Volcanic or Effusive Rocks Magma crystallized at surface

	<i>Granite</i>	<i>Rhyolite</i>
Intermediate Magma		
	<i>Diorite</i>	<i>Andesite</i>
Mafic Magma		
	<i>Gabbro</i>	<i>Basalt</i>
Ultramafic Magma		
	<i>Peridotite</i>	<i>Komatiite</i>

Geological Data, Fig. 1 Classification diagram for acid plutonic rocks containing more than 10% of quartz. This classification is based on the relative abundance of feldspars (Or orthoclase, Ab Albite, An Anorthite)

circulation of interstitial waters, sediments are subjected to a series of physical and chemical processes called ► [diagenesis](#) that transforms them into hard sedimentary rocks (sand → sandstone). The main classification schemes are based on the chemical nature of the sediment, its genesis, or its depositional environment. The most used is the one based on the genetic processes:

1. *Clastic (or detrital) rocks*: they are formed by the transport and accumulation of solid particles (detritus or clasts). There exist around 50 classification schemes for the clastic and particularly silico-clastic rocks; the most known is the one based on the size of the solid particles composing the rocks. For small particles ($<63\ \mu\text{m}$), clastic rocks are called “lutite” or “pelite” (older term). Shales or clays (composed of clay minerals or phyllosilicates) are typical lutites. For particles with intermediate size ($2\ \text{mm} < \text{particle} < 63\ \mu\text{m}$), the rock is called “arenite.” Sandstone is the typical rock of this class. For particle sizes bigger than 2 mm, the rock is called “rudite.” Conglomerates and breccias are the most widespread rudites.
2. *Chemical rocks*: they are generated by direct precipitation of ions dissolved in seawater or lacustrine water when they reach conditions of supersaturation. Rocks are generally deposited in the form of salts such as gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$), halite (NaCl), or sylvite (KCl). The resulting rocks are called evaporites. Precipitation of ions can be produced also by physicochemical changes in the environment such as precipitation of inorganic chert (Precambrian cherts) from hydrothermal fluids.
3. *Biogenic or biochemical rocks*: they are also formed by the precipitation of ions in water, but contrary to chemical cherts and evaporites, this precipitation is controlled by organisms (biochemical). This is the case for most carbonate rocks which are precipitated as calcite or aragonite (CaCO_3) or more rarely silica (by radiolarians and sponges) to form the skeletons of marine and lacustrine organisms. After the death of these organisms, the accumulation of shells can result in sedimentary rock (bioclastic carbonates or modern cherts). The accumulation and progressive transformation (diagenesis) of organic matter into sedimentary rocks can generate fossil fuels such as coal, bitumen, and petroleum (Fig. 2).

Geological Data, Fig. 2 Diagram illustrating the principles of the sedimentary rock classification. Photos represent examples of clastic rocks (*left*), chemical rocks (*center*), and biogenic rocks (*right*). (Photos H. Martin)

Geological Data,

Fig. 3 Metamorphic rock (gneiss) showing a near-horizontal foliation. Black crystals (mica) have been all recrystallized perpendicular to the direction of the main pressure. The large feldspars (white crystals) are also deformed to follow the foliation plan. (Photo H. Martin)

Metamorphic Rocks

Metamorphic rocks are igneous or sedimentary rocks that are transported, often driven by plate tectonics, in environments where temperature (T) and pressure (P) are different from the surface of Earth. A classic example is when basalts from the oceanic crust are transported deeper into the lithosphere in subduction zones. Minerals that were stable at the Earth's surface P, T conditions will become unstable and be replaced by new mineral species. All transformation reactions take place at the solid state. They are often accompanied by change in the texture of rocks, and thus, planar minerals such as mica or acicular minerals like amphiboles and pyroxenes will be reoriented perpendicular to the main pressure direction delineating a preferential orientation plan called "foliation" (Fig. 3). Three metamorphic regimes exist:

- *Shock metamorphism*: the less common when rocks are affected by a rapid change of pressure (ultrahigh pressure) caused by the impact of an asteroid or comet at the surface of Earth or of other rocky planets and moons.
- *Contact metamorphism*: refers to changes in a rock at contact – therefore heated – by a magma intrusion. Changes are controlled mainly by the increase in temperature. Marble – formed by contact metamorphism of limestone – is a classic example.
- *Regional metamorphism*: refers to changes in a rock affected by contemporary increase in temperature and pressure. Typical environments are orogenic belts and subduction zones. Gneiss is the typical rock.

Pending the origin of the protolith (i.e., the original rocks), geologists generally add the term ortho- and para- for defining metamorphic rocks derived from igneous and sedimentary rocks, respectively. A gneiss derived from a granite will be called an orthogneiss, while a gneiss derived from argillaceous sediments will be termed as paragneiss (Table 2).

Geological Data, Table 2 Some common metamorphic rocks (Photos H. Martin)

Mica schist Consists in a mineralogical assemblage of mica and quartz, without or with very few feldspars. The abundance of mica crystals draws a planar structure called foliation.		
Gneiss Quartz- and feldspar-bearing metamorphic rock, which also often contains micas. Depending on its origin, it is called paragneiss (metamorphosed sediment) or orthogneiss (metamorphosed granitic rock).	Paragneiss	
	Orthogneiss	
Amphibolite Mainly made up of amphibole and plagioclase feldspar, it can occasionally contain quartz. It generally results from the metamorphism of basalts.		
Eclogite A rock consisting in an assemblage of garnet (red) and pyroxene (green). It is generated by high-pressure metamorphism of a basalt. For instance, during progressive subduction, oceanic basalts are transformed into amphibolites, then into garnet-bearing amphibolites, and finally into eclogites (sample F. Cariou).		

(continued)

Geological Data, Table 2 (continued)

Migmatite	
At high temperatures, during the process of anatexis, a gneiss begins to melt, giving rise to small veins of granitic magma. Such a partially molten rock is called migmatite. The picture shows white veins (granitic liquid) associated with black levels that are the unmelted residues of fusion.

Eon	Phase	Age (BP)	Error	Time	Duration	Event	Comments about these events
PROTEROZOIC	Later evolution of Earth and Life (2.2 - 0.54 Ga)	542–520 Ma				Large morphological diversification of metazoans (pluricellular Eukaryotes)	
		542 Ma				First major biological crisis among Eukaryotes	Extinction of soft body fauna
		555 Ma				First mineralized animal	Several calcified macroscopic metazoans (Cloudina, Namacalathus,...)
		580–542 Ma				Ediacara fauna, first large and complex organisms, first calcified organisms around 550 Ma	Bloom of soft body fauna after last glaciation event
		580 Ma				Gaskiers glaciation	Glaciation is probably less intense?
		599–584 Ma				Doushantuo fossils	Phosphatized animal embryos, florideophytes red algae
		635–600 Ma				Marinoan glaciation	Snowball Earth probably triggered by an increase of bioproductivity and atmospheric O ₂ and the consequent decrease of atmospheric CH ₄ and CO ₂
		640 Ma				First traces of the Ediacara-type fossils: Twitya discs; possible biomarkers of sponges or sponge ancestors	
		725–710 Ma				Sturtian glaciation	Snowball Earth probably triggered by an increase of bioproductivity and atmospheric O ₂ and the consequent decrease of atmospheric CH ₄ and CO ₂
		750 Ma				1st testate amoebae	Population of various morphotypes of VSM (vase-shaped microfossils) preserved as pyritic or phosphatic molds
		780–620 Ma				Protist scales	Mineralized ornamented and perforated microscopic scales preserved in cherts
		1 Ga				Possible reptation traces made by large protists. First possible Vaucheriale (multicellular) algae	Exquisite preservation of diverse organic-walled microfossils (including protists and the multicellular vaucheriale algae) in the Lakhanda Fm, Siberia
		1.2–0.70 Ga				Supercontinent Rodinia formation then breakup	Evidence from paleomagnetic data, chemostratigraphy (carbon isotopes)
		1.2–0.75 Ga				1st multicellular eukaryotes: Bangiophyte red algae. Other multicellular algae, Cladophorale green algae and Vaucheriale algae, also occur in the 750 Ma shales in Spitsbergen and other localities	The 1st fossil eukaryote that can be related to an extant group

Dating methods	Relevant observations	Reliability	Consequence for the origin of life and evolution	Referenced entries
	Burgess Pass (Canada) and Chengjiang (china) fauna	Well-documented, many fossils	Numerous new species and animal body plans, including worms, arthropods, sponges	Burgess shale fauna; Chengjiang fauna; Eukarya; Evolution (biological); Biodiversity
	Disappearance of soft body organisms fossils			
	Nama Group, Namibia; and in other localities worldwide		Animal biomineralization	
	Traces and fossils of soft body organisms worldwide			Ediacara fauna; Ediacaran period
Stratigraphic ages estimated based on isotopic profiles ($^{13}\text{C}/^{12}\text{C}$ or $^{87}\text{Sr}/^{86}\text{Sr}$)	Accumulation of glacial sediments		Environmental stress, with possible evolutionary consequences (extinctions, radiations)?	Glaciation
Radiometric ages	Preservation by phosphatization or as carbonaceous compressions		Diversification of red algae, first animal traces	
	Accumulation of glacial sediments		Environmental stress, with possible evolutionary consequences (extinctions, radiations)?	Snowball Earth; Glaciation
			Possibly first animal record	Ediacara fauna; Ediacaran period
	Accumulation of glacial sediments		Environmental stress, with possible evolutionary consequences (extinctions, radiations)?	Glaciation
Radiometric datings	Chuar Group, Arizona; and other localities	Diverse localities; population of diverse morphology of protists with a test related to filose and lobose amoebae	Appearance of supergroup Amoebozoa; direct evidence for heterotroph eukaryotes, possible protist biomineralization	
	Tindir Group, northwest Canada		Protist biomineralization	
			Appearance of supergroup Heterokonts	
			Impact on ocean chemistry and circulation, may affect evolution of life	Rodinia
Age not well constrained but most probably 1–1.2 Ga based on chemostratigraphy and lithostratigraphic correlation	Implies earlier origin of unicellular red algae	Single locality but occurrence as population, characteristic radial cellular division, presence of holdfast	Evidence for eukaryotic multicellularity, eukaryotic photosynthesis, sex, appearance of supergroup Plantae	Eukaryotes, origin and early evolution of

(continued)

Eon	Phase	Age (BP)	Error	Time	Duration	Event	Comments about these events
PROTEROZOIC	Later evolution of Earth and Life (2.2 - 0.54 Ga)	1.5 Ga				Eukaryotic microfossils	Population of smooth-walled, and ornamented acritarchs; first spiny acritarchs (acanthomorphs)
		1.80–1.65 Ga				Eukaryotic microfossils	Population of smooth-walled and ornamented acritarchs
		1.8 Ga				Deep ocean still anoxic	Deep ocean may have remained anoxic until 0.6 Ga
		1.9 Ga				Possible iron bacteria and other microorganisms	Complex microbial communities at interface between oxygenated and ferruginous waters, in stromatolitic and non-stromatolitic cherts
		2.1 Ga				Oldest non-stromatolitic microfossils	Pyritized complex form of probable multicellular colonies of macroscopic size in oxygenated marine waters
		2.15–2.1 Ga				Cyanobacteria (confirmed)	Indisputable microfossils (colonies, akinetes) of photosynthetic aerobic organism (cyanobacteria)
	Towards oxygenation of the atmosphere (2.5 to 2.2 Ga)	2.2 Ga				Increase of atmospheric O ₂	After 2.2 Ga, the O ₂ level remains above 1% PAL
		2.2 Ga				Major glaciation event recorded in the Transvaal Supergroup of South Africa, considered as the first Snowball Earth	Probably triggered by a rise of O ₂ and consequent decrease of atmospheric methane
		2.25–2.05 Ga				Increase of bioproductivity	Oxygenic photosynthesis becomes a major biochemical process
		2.32 Ga				First evidence for atmospheric oxygen	pO ₂ < 10 ⁻⁵ PAL before 2.32 Ga, and > 10 ⁻⁵ after
		2.45–2.22 Ga				2.5–2.2 Ga, three episodes of glaciations in the Huronian Supergroup of Canada	

Dating methods	Relevant observations	Reliability	Consequence for the origin of life and evolution	Referenced entries
Radiometric datings	Microfossils from the 1500 Ma Roper Group, northern Australia		Evolution of eukaryotic nucleus and cytoskeleton	Acritarchs
Radiometric datings	Large spheromorphs with medial split opening structures (cyst opening) and one ornamented spheromorph with concentric striations, in shales from China, Australia		Unicellular Eukaryotes	Eukaryotes, origin and early evolution of; Acritarchs
	Last Banded Iron Formation (BIF)			Banded Iron Formation
	Gunflint formation, Ontario, Canada; and other worldwide localities	Widespread record	Abundant filamentous and coccoidal microfossils, but also unusual morphologies	Gunflint microbiota; Gunflint Formation
Radiometric datings	Franceville group, Gabon		Biological affinities unknown	
Radiometric datings	Belcher group, Canada (2.15 Ga); Franceville group, Gabon (2.1 Ga)		Oxygenic Photosynthesis	Cyanobacteria
	Paleosols			
	Diamictite deposits			
	Worldwide excursion of $\delta_{13}\text{C}$			Photosynthesis
	Transition from mass-independent to normal mass dependent fractionation of S isotopes (implies an O_3 layer)	The corresponding O_2 level is inferred from a photochemical model of the atmosphere (Pavlov and Kasting 2002)		Oxygenation of the Earth's atmosphere
Radiometric age of the crosscutting Nipissing mafic dyke	Diamictite deposits		-Separates oceans. -When deglaciation occurs large amounts of nutrients appear -Might be one reason for the progress of photosynthesis (very hypothetical)?	Glaciation

Eon	Phase	Age (BP)	Error	Time	Duration	Event	Comments about these events
ARCHEAN	Emergence of life and its context (3.8 - 2.5 Ga)	2.5 Ga				Biochemical indicator of Cyanobacteria and eukaryotes	
		2.7 Ga				"Golden Age" of methanotrophs	
		2.7 Ga				Unambiguous presence of life	
		2.7 Ga				Major episode of crustal growth. Formation of a super-continent	Huge volumes of juvenile continental crust were generated. This period (2.7–2.5 Ga) is also the moment when Earth dynamics changed from archaic to modern (similar to today's dynamics)
		2.7 Ga				Disputed evidence for cyanobacteria, eukaryotes and local availability of O ₂	
		2.8–2.7 Ga				Possible oxidizing event	No trace of atmospheric O ₂ , though
		2.9 Ga				First evidence of glaciation in the form of diamictite deposits in the Pongola Supergroup of South Africa	
		3.2 Ga				First cellular organic-walled microfossils	Biogenicity, endogenicity and syngenicity of microfossils are evidenced but their biological affinity is unknown
		3.2 Ga				First evidence of microbial mats in terrigenous sediments	Microbial mats occur in the intertidal photic zone so could be photosynthesizers but their biological affinity is unknown

Dating methods	Relevant observations	Reliability	Consequence for the origin of life and evolution	Referenced entries
	Occurrence of 2-methylhopanoids and steranes in rocks and in fluid inclusions and filamentous microfossil resembling cyanobacteria		Possible existence of cyanobacteria and oxygenic photosynthesis, and eukaryotes	Cyanobacteria
	Very negative values of $\delta^{13}\text{C}$ in sediments, comparable to those produced by methanotrophic organisms		If true, methanotrophy and methanogenesis had already evolved	Archean traces of life
	Well described macrofossils (fossil stromatolites), microfossils and molecular fossils	Wide consensus about their fiability	Occurrence of microbial communities covering extensive areas on the planet	Archean traces of life; Stromatolites
U-Pb zircon dating, Rb-Sr and Sm-Nd radiometric ages on whole rocks	Volumes of continental rocks of this age. Change in magma composition (end of komatiites and TTG), in tectonic style		From geological point of view, the Earth more or less behaved as the modern Earth	Crust
	Hopanes and steranes	Possible contamination – interpretation debated	Possible presence of O_2 producers and consumers and of eukaryotes, O_2 available locally	Cyanobacteria; Archean traces of life; Eukarya
	N and Fe isotopes	Requires more data and a general interpretation	Possible indication of oxygenic photosynthesis	Cyanobacteria
	Diamictite deposits			Glaciation
Radiometric age (U-Pb zircon dating) of intrusions below, through, and on top of the host rock	Up to 300 μm in diameter spheroidal organic-walled microfossils and negative values of $\delta_{13}\text{C}$ compatible with a biological origin, in shallow marine shales and siltstones of the Moodies Group, BGB South Africa		Possible planktonic life, large single cells or empty colonial envelopes	Barberton Greenstone Belt; Archean traces of life; Acritarchs
Radiometric age (U-Pb zircon dating) of intrusions below, through, and on top of the host rock	Microbial mat structures and negative values of $\delta^{13}\text{C}$ compatible with a biological origin, in intertidal sandstone of the Moodies Group, BGB South Africa		Widespread possibly photosynthetic microbial mats along siliciclastic shorelines	Barberton Greenstone Belt; Archean traces of life

(continued)

Eon	Phase	Age (BP)	Error	Time	Duration	Event	Comments about these events
ARCHEAN	Emergence of life and its context (3.8 - 2.5 Ga)	3.2 Ga				Possible prokaryotic filaments in hydrothermal deposits	Curved morphologies, exhibit putative biological behavior including preferred orientations, clustering and intertwining in rocks is interpreted as evidence for biological origin
		3.446 Ga				Possible microbial mats	
		3.46 Ga				First undisputable evidence of emerged continent	
		ca. 3.5 Ga				Potential occurrence of the oldest life traces	
		ca. 3.5 Ga				Ocean temperature of ~70 °C	
		3.7 Ga				Possible local oxidizing conditions associated with oxygenic photosynthesis	

Dating methods	Relevant observations	Reliability	Consequence for the origin of life and evolution	Referenced entries
Radiometric age (U-Pb zircon dating)	Filamentous microstructures replaced by pyrite in deep sea, volcanogenic, massive sulfides deposits in Australia	Await supporting lines of geochemical evidence	Possibly documenting thermophilic, chemotrophic prokaryotes in hydrothermal vents	Archean traces of life; Microbial mat
	Silicified mat structures including carbonaceous material with isotopic fractionation of carbon and sulfur compatible with life, in Pilbarra, Australia		Possibly indicating the presence of a variety of organisms including photosynthesizers (pelagic as well as sessile), heterotrophs, and chemotrophs	Barberton Greenstone Belt; Microbial mat
U-Pb radiochronology (on zircons)	Detrital sediments lying unconformably over an eroded basement	The clastic sediments deposited in Barberton belt (South Africa) as well as before (3.872 Ga) in the Isua belt (Greenland) probably originated from an emerged continent	Emersion of continents can favor the transfer of chemical elements and nutrients from continental crust to ocean. Ocean/continent interface is propice to the development of new habitable niches (pools, lakes...)	Continents
	(1) Possible fossil stromatolites (macroscopic) (2) Presence, although highly discussed, of morphological microfossils (3) Isotopic measurements and chemical analyses of kerogen in Archaean rocks (Pilbara craton and Barberton Greenstone Belt)	Putative microfossils are highly controversial; biogenicity of stromatolites is debated	Life and perhaps autotrophic organisms might have existed already	Archean traces of life; Stromatolites
	^{18}O and ^{30}Si fractionation are consistent with a hot Archean ocean	Debated, measures were done on chert such that they could reflect the temperature of hydrothermal system and not of the whole ocean	If true, hot water would favor thermophile-type forms of life	Precambrian oceans, temperature of
	C isotopes	Debated	Possible indication of oxygenic photosynthesis	Archean traces of life

(continued)

Eon	Phase	Age (BP)	Error	Time	Duration	Event	Comments about these events
ARCHEAN	Emergence of life and its context (3.8 - 2.5 Ga)	3.75 Ga				Possible first evidence of hydrothermal or marine water	
		ca. 3.8–2.5 Ga		From the last common ancestor to the diversification of bacterial and archaeal lineages	Not known	Diversification of energy and carbon metabolisms simultaneously to that of prokaryotic groups	The relative order of emergence of the different metabolic pathways and the time required for their evolution is unknown. This process led to many different prokaryotic (archaeal and bacterial) lineages with specific and/or versatile metabolic capabilities
		ca. 3.8 Ga				Potential occurrence of the oldest traces of life	Life, and particularly, autotrophic organisms are present
		ca. 3.8 Ga				Potential evidence of a suprasubduction ophiolite	

Dating methods	Relevant observations	Reliability	Consequence for the origin of life and evolution	Referenced entries
Radiometric age on the host rock	Fluid (water) inclusions in quartz globules in pillow basalts (assumed to represent oceanic floor) from Isua (Greenland)	Isotopic water composition may have been modified by metamorphism or by reaction with basalt	Liquid water: offers the possibility to analyze early water composition (high salinity)	Precambrian oceans, temperature of
	Based on different evolutionary scenarios, eventually supported by a few isotopic observations, inferred from the contemporary diversity of prokaryotes and their metabolisms			Archea; Bacteria; Evolution (biological); Last Universal Common Ancestor; Phylogeny; Metabolism
	Negative values of $\delta^{13}\text{C}$, comparable to those generated, today, by autotrophic organisms (either photosynthesizers or chemoautotrophs), detected in 3.8 Ga West Greenland sedimentary rocks	Highly controversial	Autotrophic organisms would have had to evolved earlier	Archean traces of life; Isua Supracrustal Belt; Akilia
	Existence of almost all components of an ophiolite: ultramafic rocks, gabbros, dyke complex, pillow lavas	Debated	Existence of modern-like plate tectonics	Precambrian oceans, temperature of

Eon	Phase	Age (BP)	Error	Time	Duration	Event	Comments about these events
HADEAN ← ARCHEAN → PROTEROZOIC	Prebiotic chemistry, biochemistry and emergence of life (4.4 - 2 Ga)			From the emergence of the first life form to the diversification of the different domains of life	Not known	Series of very important events, but their chronology (absolute and relative) remains totally unknown	Membranes: No data are available for the appearance of the first membranes. The class of amphipathic molecules that were involved (fatty acids, terpenoids, peptides or other compounds) is unknown
							Genetic information and translation: coupling of metabolism (energy, organic matter) and the genetic system (information). Emergence of the genetic code (and then of coded proteins and enzymes). Last common ancestor Origin of viruses (polyphyletic origin). Transition from RNA to DNA
							Metabolisms: the sequence through which energetic metabolisms and carbon metabolic pathways developed is unknown. Anaerobic metabolisms: fermentation, anaerobic respiration, anoxygenic phototrophy

Dating methods	Relevant observations	Reliability	Consequence for the origin of life and evolution	Referenced entries
None		No information is available about the appearance of the cytoplasmic membrane	The cytoplasmic membrane may have been present either at early stages for a life form based on the compartmentalization of a protometabolism or may have been developed later in evolution if a mineral surface ensured a reduced number of degrees of freedom or if encapsulation was not absolutely needed (e.g., RNA world)	Cell; Cell Model; Origin of life; Life; Oparin's Conception of the Origin of Life
		The problem of the first genetic system is still unsolved	First genetic system: <i>Hypothesis1</i> : stage in which RNA played both the roles of information carrier and coded catalyst (RNA world) but there is no available abiotic synthesis of nucleotides and RNA. <i>Hypothesis2</i> : Stage preceding the RNA world (pre-RNA world) based on earlier information carriers that left no traces during further evolution (no indication available). <i>Hypothesis3</i> : coevolution process involving amino acid and nucleotide chemistries and leading directly to the emergence of the translation machinery	RNA World; Nucleic acids; Genetic code; DNA; Virus; Last Universal Common Ancestor; Evolution (biological); RNA; Protein; Genome; Ribosome; Replication (genetics)
		The initial energetic metabolisms proposed are model-dependent. There is no consensus and no certainty about the nature of the oldest metabolic pathways (three of four pathways for carbon fixation have been suggested)	Production of energy: most energy metabolisms of early living beings possibly emerged and diversified very rapidly and simultaneously. Anoxygenic photosynthesis may have preceded oxygenic photosynthesis. Possible initial energetic metabolisms: if life emerged from a prebiotic soup (heterotrophic and cold origin), then fermentation likely came first. If life emerged in hydrothermal systems (autotrophic and hot origin) then, it may have been based on oxidoreduction processes. Development of carbon metabolism	Bioenergetics; Metabolism

Eon	Phase	Age (BP)	Error	Time	Duration	Event	Comments about these events
HADEAN ← ARCHEAN — PROTEROZOIC →	Prebiotic chemistry, biochemistry and emergence of life (4.4 - 2 Ga)	4.4–3.8 Ga or later		After the formation of the atmosphere and oceans and after the cessation of deleterious processes such as (irradiation, bombardments, excessive temperature. . .) – before the emergence of the first life form	Unknown	Series of very important events, but whose chronology (absolute and even, to some extent, relative) remains unknown	Chemical evolution. Formation of complex assemblies of molecules [covalently-bound polymers (peptides, polysaccharides, oligonucleotides or analogues) and/or non-covalently-bound structures (liposomes, vesicles, etc.)] from available species and energy and/or emergence of protometabolisms possibly involving the activity of mineral surfaces but needing a confined environment
							Prebiotic chemistry. Chemical synthesis starting from organogenic molecules and/or energy-releasing molecules and/or energy sources. Depending on the model, reactions occurring in solution or after adsorption and/or concentration on inorganic surfaces or in inorganic microcavities. Availability of a varied set of organic molecules and of biomonomers (“prebiotic soup”): amino acids, sugars, nucleic bases, nucleosides, polyphosphates, etc.
							Supply of organic molecules and energy. Synthesis in the atmosphere (perhaps in a reducing one) of low-molecular-weight organogenic molecules (H ₂ CO, CO, NH ₃ , H ₂ S, HNCO, HCN, etc.) and/or exogenous delivery (infall of meteorites, comets) and/or generation of organic molecules during hydrothermal activity or through reactions on clay mineral surfaces

Dating methods	Relevant observations	Reliability	Consequence for the origin of life and evolution	Referenced entries
None	The presented stages correspond to more or less plausible scenarios based on the present knowledge of the primitive Earth and on what is known about chemical reactivity in such environments		The increase of complexity may have involved different stages following one another in sequence or resulted from an emergence process without clearly delimited steps. Anyway, a crucial phase led to a self-sustained entity carrying both a metabolism and the information content needed for its self-reproduction at the initial stage of Darwinian evolution	Complexity; Self-replication; Self assembly; Polymer; Lipid bilayer
			Depending on the family of compounds, more or less plausible chemical pathways are available for the formation of amino acids, sugars and nucleic bases. There abiotic synthesis of nucleotides remains somewhat problematic	Formaldehyde; Formose reaction; Ammonia; Amino Acid; Ocean, chemical evolution of; Earth atmosphere, origin and evolution of; Oceans, origin of; Precambrian oceans, temperature of; Earth, formation and early evolution; Earth, surface evolution; Amphiphile; Nucleic acid base; Chirality
				Late heavy bombardment; Extraterrestrial delivery (organic compounds); Meteorites; Comets; Abiotic photosynthesis; Photochemistry; Electric discharge; Photochemistry, atmospheric; Fischer-Tropsch Type Reaction; Hydrothermal reaction; Hydrothermal environments

Eon	Phase	Age (BP)	Error	Time	Duration	Event	Comments about these events
ARCHEAN HADEAN	Building of a habitable planet (4.55 - 3.8 Ga)	3.817 Ga	± 0.016 Ga			First post LHB (Late Heavy Bombardment) rocks; Important episode of crustal growth (at least in Canada and Greenland)	The existence of sedimentary rocks imply the existence of liquid water (ocean) and of continents. At Isua, clastic sediments are interpreted as evidence of emerged continents. First huge continent (Super-continent?) existed. A modern-like global geological and probably geodynamic system already in place
		3.863 Ga	± 0.012 Ga				
		3.872 Ga	± 0.010 Ga				
		3.9–3.8 Ga				End of LHB (Late Heavy Bombardment)	
		4.031 Ga	± 0.003 Ga			The oldest known rock (it survived the Late Heavy Bombardment)	This continental crust is TTG ("granitic") in composition
		4.1 to 3.9–3.8 Ga			< 200 Ma at most, > 20 Ma at least	"Late Heavy Bombardment" (LHB)	Intense bombardment episode on the Moon. This phenomenon, observable on the Moon is considered has having also taken place on Earth
		4.2 Ga				Putative oldest Hadean continental crust in Canada	
		4.4–4.0 Ga				Genesis of huge volumes of continental crust (at 4.0 Ga about 15% of the present day continental crust volume was formed)	A recycling process of continental crust existed
				$T_0 + (100\text{--}150 \text{ Ma?})$		Late veneer (dusts, bolides) especially carbonaceous chondrites	Exogeneous supply of H, C, N, O, S, P
		4.4–4.37 Ga		$T_0 + 170 \text{ to } 200 \text{ Ma}$		First proto-oceans	

Dating methods	Relevant observations	Reliability	Consequence for the origin of life and evolution	Referenced entries
U–Pb radiochronology (on zircons), Rb–Sr and Sm–Nd radiometric ages on whole rocks	Zircon crystals extracted from Nuvvuagittuq (Purpose Cove) volcanics and whole rocks			Nuvvuagittuq (Porpoise Cove) Greenstone Belt
	Zircon crystals extracted from Uivak gneisses and whole rocks			
	Zircons. Ultramafic rocks, sediments, including clastic sediments (Akilia, Isua, Amitsoq); BIF (Akilia et Isua) Huge volumes of TTG (which implies a “granitic” continental crust)			Isua Supracrustal Belt
	Rocks contain marine fluid (water) (–3.8 Ga), age of the great lunar basins		Potential life can be envisaged	Isua Supracrustal Belt; Late Heavy Bombardment
U–Pb radiochronology (on zircons)	U–Pb ages on zircon crystals extracted from the rock. The Acasta gneisses are the oldest rocks discovered on Earth, they represent the oldest continental crust. One Acasta zircon gave an age as old as 4.065 ± 0.008 Ga		Acasta gneisses formed during the LHB and avoided total destruction. As some parts of continental crust escaped destruction during LHB, possibly, some pre-existing forms of life could also have survived	Acasta gneiss
U–Pb radiochronology (on lunar rocks)	Dating of lunar impact craters and their relative chronology. The model more widely accepted today considers that bombardment had a maximum at about 3.9 Ga		Planet re-surfacing, most existing structures were likely destroyed, including both oceans and continents	Late Heavy Bombardment
U–Pb radiochronology (on zircons)	Dating of inherited zircon cores in Acasta gneisses		At least some parts of the Hadean crust survived the LHB	Acasta gneiss; Late Heavy Bombardment
U–Pb radiochronology (on zircons)	U–Pb ages on Jack Hills and Narryer zircons; these crystals display zones of different ages indicating several episodes of crystallization at different epochs		Huge fragments of stable continental crust existed	Archean Eon; Earth, formation and early evolution
Models	Presence of volatile species (e.g., CO ₂ , H ₂ O) on Earth despite the very high temperature during the planet accretion phase		Biogenic elements available	Late Veneer; Water delivery to Earth; Earth atmosphere, origin and evolution of
	Based on the oxygen isotopic composition of zircons and on physical models for Earth formation		Huge volumes of liquid water	Oceans, origin of; Earth atmosphere, origin and evolution of

Eon	Phase	Age (BP)	Error	Time	Duration	Event	Comments about these events
HADEAN	Building of a habitable planet (4.55 - 3.8 Ga)	4.404 Ga	± 12 Ma			Genesis of the first continental crust, "granitic" in composition	Free water (proto-ocean) is necessary on Earth surface. If $P = 270$ Atm, the temperature can be as high as 500 K. If $PCO_2 = 25$ Atm, temperature as low as 380 K.
				$T_0 + 10$ to 70 Ma		External supply of water	
				$T_0 + 100$ Ma		Atmosphere formation	
				$T_0 + 0.1$ Ga? or $T_0 + 2$ Ga?	Few 100 Ma	Accretion of the Earth magnetic field	
	The first 100 million years: The "Telluric Planet Formation" era			Roughly $T_0 + 30$ to $T_0 + 150$ Myr	Very fast: timescale of days	Formation of the Moon from a Mars-sized impactor, sometimes called Theia	The Moon-forming impact is thought to have been the last giant impact suffered by the Earth during its formation
					100–200 Myr	Magma ocean + core segregation	Differentiation inside the magmatic ocean, formation of a proto-crust
						Primitive atmosphere	
				$T_0 + 10$ to 100 Myr	10–100 Myr	Formation of the Earth by collisional accumulation of planetary embryos and planetesimals	This is dated by $^{182}\text{Hf}/^{182}\text{W}$ radiochronology (half-life of 9 Myr), which roughly measures the time of the last core-forming episode, i.e., differentiation. This is thought to have been caused by the Moon-forming impact – the impactor is sometimes called "Theia"
				$T_0 + 10$ to 10 Myr		Formation of Mars	Differentiation of the planet (+magmatic ocean?)

Dating methods	Relevant observations	Reliability	Consequence for the origin of life and evolution	Referenced entries
U–Pb radiochronology (on zircons)	Core of zircon crystals from Jack Hills: they represent the oldest known terrestrial materials. The measured age is the age of the minerals (the host rock is unknown). Zircons crystals contain inclusions of minerals abundant in granites (quartz, feldspar and mica). Oxygen isotopes determined in these zircons give high $\delta^{18}\text{O}$		Emersion of the first continental masses. The amount of available liquid water could have been either small and very localized or generalized (ocean)	Cool Early Earth; Oceans origin of; Jack Hills; Earth, formation and early evolution
				Water, delivery to Earth
Radiochronology, Solar System dynamic models	Xe isotopes in atmosphere and mantle			Noble gases; Earth atmosphere, origin and evolution of
Theoretical models			Partly protects Earth surface from ionizing particles (cosmic rays) Able to indirectly favor or to disfavor some chemical reactions	
^{182}Hf – ^{182}W radiochronology	Cf. Earth's formation		Many possible (but disputed) influences of the Moon on the life evolution	Moon
^{146}Sm – ^{142}Nd and Pu–Xe radiochronology	The rocks of Isua (3.8 Ga) have recorded an early fractionation of ^{142}Nd , explainable by a magmatic ocean			Magma ocean
Theoretical models	None	Hypotheses		Atmosphere, primitive envelope
^{182}Hf – ^{182}W radiochronology	(1) Last metal silicate equilibrium on Earth registered at 30 Ma (^{182}Hf – ^{182}W ; uncertainty range 11–50 Ma); this might correspond to the Theia impact (2) Age of 45 Ma for lunar crustal differentiation (3) N-body models of telluric planet formation from planetary embryos		Core formation may have allowed Earth's magnetic field to arise, limiting the flux of potentially damaging high-energy particles on the surface. In addition, the Moon stabilizes the Earth's obliquity (although only after causing the Earth's spin period to increase to more than ~10 h).	Planetary embryos; Planetesimals; Late-stage accretion
	Isotopic analyses of meteorites originating from Mars		The differentiation is a major heat source. It influences the planetary structure, the cooling and the surface temperature. Later crust composition and volcanism	Mars

Eon	Phase	Age (BP)	Error	Time	Duration	Event	Comments about these events
HADEAN	The first 10 Ma: The “Protoplanetary Disk” Era			T_0 + a few (3–10) million years	100,000 to a few million years (timescale for gas dispersal)	Disappearance of first generation accretion disks (i.e., gaseous disks). For solar-like stars, start of the diskless, “post-T Tauri” phase	The gas lifetime sets an upper limit on the formation timescales of gas giant planets. Age of oldest disks ~10 Myr
				T_0 + 1 to +10 Myr	Few million years	Likely formation of Giant Planets (for the Sun: Jupiter and Saturn, perhaps also Neptune)	The formation of giant planets takes place either from a core or from a gravitational instability in the disk. In the first case, the formation of the core itself starts from planetesimals, according to a process similar to (but faster than) telluric planets, and in parallel with them
				From T_0 until the dust disappears	5 Myr	Formation of km-sized “planetesimals” and ~Moon-sized “planetary embryos”	Recent models suggest that the gas in the disk helps to form planetesimals by concentrating mm- to m-sized objects into gravitationally-bound aggregates. Planetary embryos form planetesimals, and constitute the true building blocks of terrestrial planets and giant planet cores
		4.568–4.567 Gyr	±0.5 Myr	T_0	5 Myr	Formation of the first solids in the solar system (Chondrules, CAIs, some differentiated meteorites...)	CAIs (Calcium-Aluminum inclusions) are considered to be the oldest solids. In CV chondrites, they formed in less than 50,000 years. Most chondrules are 1.5 Myr younger than CAIs, though some formed within 0.5 Myr. The first differentiated bodies may have formed during this disk phase, contemporaneously with CAIs. This phase lasted ~5 Myr

Dating methods	Relevant observations	Reliability	Consequence for the origin of life and evolution	Referenced entries
Statistical models and observations	Direct observations of circumstellar disks around young stars are made at infrared to far-infrared wavelengths (dust), and submillimeter to mm wavelengths (cold molecular gas). Disks can also be seen in silhouette in case of a luminous background (e.g., in a bright nebula like Orion)	Circumstellar disks are spatially resolved for solar-like stars closer than $\sim 1,500$ light-years (sizes up to 500 AU), but structures smaller than ~ 10 AU cannot be distinguished yet	Stops the accretion of hydrogen in giant planets (hence: puts a limit on their mass, influences their composition, and probably the size and composition of their satellites; stops some planetary migration processes)	Protoplanetary disk; Solar nebula
Numerical models			The formation of a giant planet had a major influence on the dynamics of planetesimals, on the formation of terrestrial planets (probably), on the delivery of water, and on the “late heavy bombardment” (LHB) event	Core accretion model; Gravitational instability
Numerical methods and radiochronology based on Pb–Pb, ^{26}Al , ^{182}Hf and ^{53}Mn	Pb–Pb age of chondrules and differentiated meteorites – age of disks, and radioactive dating of iron meteorites (originating from large differentiated bodies)	Timescales and size scales in models are uncertain to 1–2 orders of magnitude but the mechanisms of planetesimal and embryo formation appear robust	The fundamental building blocks of terrestrial planets and giant planet cores. The formation time of these objects also affects their compositions: the faster they form, the more efficiently short-lived radionuclides heat them up and the less volatiles they retain	Planetesimals; Planetary embryos; Gravitational collapse; CAIs; Cosmochemistry
Radiochronology based on Pb–Pb, ^{26}Al , ^{182}Hf and ^{53}Mn	It is an assumption that CAIs age define the start of the Solar System. Some iron meteorites originating from the cores of differentiated asteroids are contemporaneous or older than CAIs according to their respective Hf–W systematics.	The individual age of CAIs is often known with a precision better than 0.5 Myr. There is however a spread in CAIs age. Because the origin of the spread is not known (analytical artifact, secondary events. . .) it is doubtful to assign a precise T_0 .	Beginning of the planet formation process, a necessary (but not sufficient!) condition for life to appear	Protoplanetary disk; Solar nebula; CAIs; Cosmochemistry

Eon	Phase	Age (BP)	Error	Time	Duration	Event	Comments about these events
				T_0 = conventional zero of the second time period = age in the case of the solar system		At T_0 , oldest dated solids formed in the solar protoplanetary disk	For the Solar System, T_0 probably took place at a time between the beginning of class 0 and the end of class I
The first million years: The "Star Formation" Era					$T_0^* + 1$ to 10 Myr	T-Tauri star: Phase 2	"Class III": end of Phase 2, disappearance of disks. This suggests a fast disk evolution between Class II and Class III. Disks disappear between 3 and 5 Myr. The reasons may be multiple: planetary formation is the leading explanation, but other phenomena like evaporation due to stellar UV and X radiation may also play an important role
				$T_0^* + 0.1$ Myr	From 1 to 10 Myr	T-Tauri star: Phase 1	"Class II": Last stages of star formation. Structured gas and dust disk (outer "flaring", i.e., thickness increasing with distance from the central star, etc.); low accretion rate ($<10^{-7}$ solar mass/year)
				$T_0^* + 0.01$ Myr	$\sim 100,000$ years	Protostar: Phase 2	"Class I" = progressive end of the strong accretion phase on the central object, which is already a (growing) star. Bipolar jet (fast ejection of gas, $v_{ej} \sim 200\text{--}400$ km/s) visible near the center, perpendicular to the dense circumstellar disk

Dating methods	Relevant observations	Reliability	Consequence for the origin of life and evolution	Referenced entries
				Protoplanetary disk; Solar nebula; CAIs; Cosmochemistry
Physical models: Hertzsprung–Russell diagram and evolutionary tracks	Spectrum and magnitude of the central star leads (like during T-Tauri Phase 1) to ages and masses determinations from their position in the HRD. Circumstellar disks are studied in increasing detail; structures (rings, spiral arms...) can be seen, which allow to study properties of dust grains and their growth; gaps, maybe due to planet formation; migration of giant planets towards the central star?	Possible reason for the evolution of circumstellar disks: planetary formation. Still poorly understood and subject of active research		T Tauri star; Debris disks; Activity (magnetic); Magnetic field; Sun (and young sun); X-rays (stellar)
Physical models: Hertzsprung–Russell diagram and evolutionary tracks	Spectrum and magnitude of the central star (now optically visible): The star can be placed on a Hertzsprung–Russell diagram (HRD), which allows to determine its age and mass from theoretical models; a few binary systems allow a fairly precise mass determination to test the models (using Kepler's laws). For 1 solar mass, at this stage the star is about 1 Myr old. Circumstellar disks are visible at all wavelengths; a collimated jet is also visible (on theoretical grounds, there is a causal relation accretion => jet, mediated by magnetic fields); Lifetime ~1 Myr (independent from the HRD determination)	Stellar masses determined within a factor of 2; uncertainties on the age may be large, depending on the location in the HRD. For ages >1 Myr, uncertainties within factors 2–3; very uncertain below	Conditions for protoplanetary disk and planet formation	Chemistry in protoplanetary disks; Turbulence (planetary disks); Activity (magnetic); Magnetic field; Radio astronomy; Stellar evolution; T Tauri star; X-rays (stellar)
Statistical models: statistics on classes and dynamical age	Age of Class 0 and Class I sources (see below): the ratio is proportional to the ratio of their respective observed numbers. Jets: the ratio size/velocity gives an estimate of the timescale for star formation (~100,000 years for 1 month); these jets are produced as a result of accretion by magnetic interactions in the vicinity of the central object	Theory very uncertain: no explanation for the accretion rate. The disk viscosity (which is necessary for accretion on the central object to take place) may be due to the “magnetorotational instability” (leading theory, but other theories exist)		Birthline; Chemistry in protoplanetary disks; Infrared spectroscopy; Magnetic field; Radio astronomy; X-rays (stellar)

(continued)

Eon	Phase	Age (BP)	Error	Time	Duration	Event	Comments about these events
	The first million years: The “Star Formation” Era			T_0^*	~10,000 years	Protostar: Phase 1	“Class 0” = massive envelope in free fall; matter concentration at the center, “accretion” on this nucleus ($\sim 10^{-5}$ month/year) and growth of a protostellar object from a disk (because of rotation) made of gas and dust grains. The duration of the “dynamical collapse” phase depends on the mass of the star ($\sim 10,000$ years for ~ 1 solar mass)
	Start of the “Collapse Era”			T_0^* = conventional origin of the first time period		Astrophysical start of the formation of the Sun	Start of the collapse of a molecular cloud core. The triggering mechanism is still unclear, probably external and not unique (turbulence, shock waves from distant supernovae, etc.) Stars are most often formed in clusters of several 100–1,000 stars

Dating methods	Relevant observations	Reliability	Consequence for the origin of life and evolution	Referenced entries
Theoretical models: dynamical collapse (free fall)	Large-scale central “bipolar” molecular outflow, perpendicular to the disk, entrained by a stellar jet. Causes angular momentum dissipation and eventually collapse. The stellar jet itself is invisible optically, because buried into dense material, but becomes visible at Phase 2. Cold envelope (30–100 K): observable exclusively at (sub) millimeter wavelengths. Size of the envelope: 1,000–10,000 AU, depending on the interstellar environment (dense or diffuse)	Theoretical modelling and collapse velocity roughly estimated in several objects. “Class 0” objects are visible only at millimeter wavelengths	Conditions for star formation fulfilled	Interstellar medium; Interstellar turbulence; Magnetic field; Radio astronomy; Star formation: the observations
	1 Myr (astronomy) $\equiv$ 1 Ma (geology) = 10^6 years
